The Summer Meeting of this Section of Laryngology of the Royal Society of Medicine was also held at the Conference, when the subjects discussed were the catarrhal child and facial paralysis. The President of the meeting, Mr. T. G. **Wilson** (Dublin), began by assuming that the term was meant to refer to inflammation of the mucosa of the upper respiratory passages. Predisposing factors to such infection included allergy, antibody deficiency, endocrine factors, heredity, environment, and perinatal infection. Mucoviscidosis, previously known as fibrocystic disease of the pancreas, was not a great rarity, occurring as it did in one in a thousand live births. Local factors were nasal and paranasal sinus infection and nasal obstruction caused by adenoids. Treatment consisted in providing and maintaining a clear airway, and this included the treatment of infected sinuses and the removal of adenoids.

Referring to the history of the word "catarrh," Dr. L. H. **Capel** (London) pointed out that Plato had deplored that the "Sons of Aesculapius" should have to invent terms like catarrh to describe a vague and faintly disreputable condition. It might be wrong to assume that the problem was entirely related to immunology and allergy, as possibly anatomical peculiarities in childhood might predispose to the condition. "Catarrhal" in this sense might be defined as that condition of the nasal airways in which an increase in secretion, or narrowing, was present. In Great Britain respiratory illness was the rule in early life, and if infections occurred early in life they tended to recur. Air pollution, social conditions, and exposure to infection in others were all epidemiological factors. The initial infection was usually viral in nature, and lowering of the outside temperature might favour its growth. Management should be directed to the treatment of infected sinuses, removal of obstructions such as adenoids, the reassurance of the parents, and the exercise of patience until puberty.

Intrauterine and Neonatal Factors

The third speaker, Dr. E. E. **Doyle** (Dublin), said that in considering intrauterine and neonatal factors infection of the liquor amnii might take place within 12 to 24 hours of the rupture of the membranes, but in fact children born after long labour showed no increased tendency to respiratory infection. Nevertheless, neonatal obstruction due to crusting was a common problem in Dublin, even to the extent of interference with suckling, though follow-up of these children showed no increased tendency to infection after the neonatal period. The allergic factor was much more common in Dublin in the lower income groups, and the problem was in general greater where overcrowding was present. Children living in these conditions often had chronically infected adenoids, tonsils, sinuses, and chronic bronchitis. It was remarkable to watch the weight gain and general physical improvement in these children when the adenoids and tonsils were removed and the sinusitis was cleared up. In older children and adolescents infection often appeared to be associated with an anatomical abnormality such as a deflected nasal septum, and vaccination against influenza in closed communities such as boarding schools served a useful purpose.

Facial Paralysis

Reviewing the causes of facial paralysis, Professor **Henry Miller** (Newcastle upon Tyne) pointed out that reassurance could be given to a patient who was believed to have had a stroke but who had weakness of the whole facial nerve; in fact the upper face escaped in supranuclear lesions, because the neurones of the facial nucleus controlling movement of the upper face received impulses from both cerebral hemispheres. Leprosy was the only cause of bilateral facial paralysis in which the upper face was more often affected than the lower. Dealing with Bell's palsy, Professor Miller emphasized that the history of an acute and non-progressive lesion, often preceded by local pain, was characteristic. A comprehensive review of world literature had yielded no single shred of scientifically valid evidence that surgical treatment exerted a favourable influence on the outcome of Bell's palsy.

Dr. **Deryck Taverner** (Leeds) emphasized that the management of Bell's palsy should be directed to accurate diagnosis, relief of pain, reassurance, accurate prognosis, and prevention of sequelae. In 10–15% of cases Wallerian degeneration occurred, with unsatisfactory recovery. The difficulty was in predicting in which cases this would occur, and he had found that anodal galvanic stimulation of the tongue, with assessment of the threshold at which a metallic taste was perceived, gave useful prognostic information in 95% of cases. Treatment with corticotrophin had been found to be so effective that he felt unable on ethical grounds to carry out further trials with untreated controls.

Surgical Approach

Professor L. B. W. **Jongkees** (Netherlands) dealt with the surgical approach to facial paralysis as a whole, pointing out its undoubted value in postoperative or post-traumatic paralysis, or paralysis associated with chronic middle-ear palsy. In particular, all cases of progressive facial paralysis should be seen by the otologist, unless there was another obvious cause. In Bell's palsy he believed that surgical decompression of the nerve should be carried out if denervation was complete, to confirm the diagnosis and to give a better chance for reinnervation to take place. He cited 200 patients in whom operation had been performed; only one patient had been dissatisfied, and then because of tinnitus.

Chemotherapy in Head and Neck Cancer

Professor D. F. N. **Harrison** (London) said that 200 patients with cancer of the head and neck had been treated under his care in the last five years. Most of them had already been treated by either surgery or some form of irradiation, or both, and the aim of chemotherapy at this stage was palliation. There had been little new in the development of chemotherapeutic agents during this time, but much had been learnt about what these agents could and could not do, and about how to avoid some of the undesirable toxic side-effects associated with their use. The powerful alkylating agent Epodyl (ethoglucid), which could be used only intra-arterially, had a life of some eight minutes; the aim must be to limit its action to a local arterial field. One of its cardinal properties was its ability almost invariably to relieve pain, by its destruction of peripheral nerve endings.

During the arterial infusion the bone marrow could be protected from damage by the cooling of the whole patient. This shunted blood away from the bone marrow and reduced the rate of metabolism in the marrow itself. Moreover, it might permit infusion into the internal carotid artery without causing cerebral damage.

Other speakers discussed other chemotherapeutic agents, including methotrexate, and the techniques of administration that might be employed. It was apparent that at present this form of treatment should be carried out only at centres big enough, and with sufficient equipment and trained personnel available, to be able to cope with the many problems and complications which may arise during treatment.

Letters to the Editor should not exceed 500 words.

Restrictions on Doctor in South Africa

SIR,—No doubt readers of the *B.M.J.* are aware of the recent "banning" orders served on Dr. R. Hoffenberg, a senior lecturer in the Department of Medicine, University of Cape Town. He is also a consultant at Groote Schuur Hospital, Cape Town, and a research worker of international standing.

Some of Dr. Hoffenberg's closer colleagues have discussed the more general aspects of the ban in the correspondence columns of *The Times*,[1] but we wish to refer here to the matter as it affects the medical profession. Dr. Hoffenberg's passport was confiscated in 1965, so that he was prevented from contributing to or learning from international conferences. Now his "banning" orders mean that he will not be allowed to teach students at the medical school or in the hospital; he will not be allowed to publish scientific material nor to attend any gathering whether academic or social.

We wish to remind the medical profession in this country that these punitive measures have been taken against Dr. Hoffenberg by the South African Government without any charge being brought against him, and he has no possibility of appeal. Dr. Hoffenberg's medical integrity is not in question, and we must therefore assume that he is being persecuted for his humanitarian work.

We trust that medical men in Britain will give all the support they can to professional bodies in South Africa should they decide to challenge the ban with the limited means available to them. Professor J. F. Brock, professor of medicine in the University of Cape Town, has already issued a statement in the strongest terms, which was published in the *Cape Times* of 2 August 1967. We have seen this statement and support Dr. Brock in his protest against the restriction of a valued member of the profession.—We are, etc.,

A Case for Cannabis?

SIR,—The marihuana psychosis reported by Dr. P. J. Dally (5 August, p. 367) is known in the literature as oneiric delirium or oneiric fantasy. I originally encountered it during my childhood in the Orange Free State, where our employees grew dagga (*Cannabis indica*) illegally and smoked the flowering tops. One of them was what contemporary marihuana smokers would call a "pot head," and was "stoned out of his mind" through smoking dagga constantly. I remember him as my first experience of a drug addict, by turns hilarious and feebly shaking, irrational, incapable of earning a living, ending his life as a grey shadow who emerged from his bundle of rags only when his wife offered him food or he needed more dagga. It is surprising to me that this condition, clearly described by various workers,[1-3] has never been mentioned in the numerous statements made by my colleagues in the popular press.[4,5]

During the past three years I have taken histories of the effects of cannabis on 40 people: some patients, and some habitués, either anxious to impress me as to its virtues or alarmed and shocked by their own physical and mental changes induced by the drug.

A pregnant girl of 16, who had taken small doses of amphetamine intermittently, smoked reefers from time to time. On one occasion she was offered black conga, a resin from North Africa, and smoked a quantity. She described herself as having felt as if she had been kicked by a horse, had terrifying nightmares, and was semiconscious the whole of the next day. She became violently antagonistic to the drug, and was taking nothing at all during psychotherapy.

Another boy left his public school at 16, and became in appearance and manner a typical junkie. He was afraid of other drugs than cannabis, but appeared to be a chronic schizophrenic during the whole period of three years' exposure to the drug. Following probation for drug possession he is in a steady job, and has lost his emaciated neglected appearance and abandoned his grandiose flights of fantasy. He does not appear to be still hallucinated.

A boy of 20 was given his first reefer outside a pub two years previously. While working as a painter and decorator he smoked a particularly strong reefer to ward off symptoms of influenza, and remained semiconscious for three days. During his exposure to the drug he behaved like a chronic mild schizophrenic, but came off the drug after being on probation and entered steady employment. Later, however, he deserted his pregnant wife to join the "Flower People."

Intermittent cannabis-smoking causes slight bronchitis, injection of the conjunctivae, and voracious appetite. Confusion, apathy, and bad temper last for two or three days, during which period barbiturates, alcohol, and phenothiazines produce quite atypical effects. The desire to work is lost, because the subject becomes sure that the job has already been mastered even if it was not really begun. Argument over this produces either a crushingly arrogant response or an extremely paranoid reaction. This change in personality trait is one on which cannabis-taking can be diagnosed in a school or a club; it is extremely striking, and takes up to two weeks to be reversed. More chronic subjects look ill and are emaciated in spite of their enormous appetites and thirst. Though they state that the drug can be easily given up, the psychic dependence appears to be similar to that of cocaine. Even a similar smell, let alone a whiff of the drug itself, excites a strong desire for a reefer. The "come down" lasts two to three weeks, and includes depression about losing the self-confidence and fantasy the drug induced.

In the early 1950s European doctors were warned by the Japanese that the amphetamine habit could produce psychosis, suicide, and major social problems.[6] Our literature has only recognized this psychiatric state recently. This is probably because the amount of habituation to this drug has only risen gradually, but also because the psychosis takes a few years to establish on the small doses of amphetamine which were normally used in Britain. Ten tablets of dexamphetamine-amytal mixture are now taken where one was taken five years ago; for this reason the psychosis develops more rapidly and is more obvious.

The original *Lancet* article "Pop Pot"[7] and the broadcast on "Today," which are quoted by pedlars to prove the harmlessness of marihuana, appeared in 1963. Dr. Dally's experiences and my own may indicate the beginning of a crop of cannabis psychotics which can increase the young population of our mental hospitals and slow down the estimated halving of this by the 1970s. Not unnaturally I become acutely apprehensive when I read authoritative articles in the popular press, signed by my colleagues, stating that this drug is less harmful than alcohol or tobacco. Until we, as doctors, can resolve our differences, we would be wise to confine our polemics to our professional journals.—I am, etc.,

London W.1. ELIZABETH TYLDEN.

SIR,—I am reluctant to add to all the ill-informed comments on drugs, but I am at a loss to understand why the therapeutic value of a drug should be considered in relation to its social usage. I am sure that Dr. D. Stafford-Clark does not intend in his letter (12 August, p. 435) to imply that because a drug has some therapeutic value this in some way makes it possible to free it from restriction, but I have no doubt that the "pot" lobby will fall upon his statement and draw from it quite disastrous inferences.—I am, etc.,

DAVID WILD,
Deputy County Medical Officer of Health.

Sussex.

Dangers of the Woulfe Bottle

SIR,—I was interested to read the article by Dr. B. J. Freedman on the value of the Woulfe bottle for the humidification of oxygen (29 July, p. 277).

In the course of time the water in these bottles can, and often does, turn into a culture of *Pseudomonas aeruginosa*. Experiments with a slit-sampler show that organisms are carried over from the bottles in oxygen bubbled through the water.

It is important, therefore, that such bottles should be washed out and sterilized at frequent intervals. The risk of contamination would be greatly reduced if, in addition, the bottles could be kept empty and dry when not in use, and water put in only when a patient needed to be given oxygen for more than a short period.—I am, etc.,

Friction is the Rub

SIR,—May I be permitted to voice a brief protest against the term "friction rub," which over the past few years has crept into the medical literature and has now achieved the distinction of appearing on the first page of the *British Medical Journal* in an otherwise most excellent leading article on "Chest Pain after Infarction" (5 August, p. 321). "Friction" and "rub" are each defined in terms of the other by all English dictionaries. Perhaps we shall soon be reading of murmur bruits and crepitation râles.—I am, etc.,

J. V. S. A. DAVIES.

Investigating Hypertension

SIR,—There is certainly need for balance in the investigation of hypertension, and I write to support the author of your leading article (1 July, p. 4). We have had a particular interest in hypertension and its investigation for twenty years, and two clinics each week are run for the management of patients undergoing long-term treatment with potent drugs. Almost all are first admitted to hospital for assessment to ensure that such a heavy life sentence is really necessary. It must be exceedingly uncommon for any potentially remediable surgical condition not to be suggested by a good intravenous pyelogram and isotope renogram, and, if significant, further investigation would be indicated by failure to respond to medical treatment. I think there may be a tendency for those with a particular interest in the surgical treatment of renal hypertension not to persist with antihypertensive drugs in appropriate combination with or without salt restriction, because our experience has been that treatment, if relatively difficult, is usually satisfactory in such cases.

The detailed investigation of 1,000 cases by aortography is impressive (Wing-Commander P. W. Robertson, 29 July, p. 306), but presumably they were mainly undertaken in relatively young, otherwise well, males.

I am sure that such a programme is justified for pure research, particularly if there is a possibility that the conclusion will be reached that such elaborate investigations are not necessary in most cases, but from the practical point of view of ordinary investigation I think that aortography is rarely required. Undoubtedly, of course, the larger the number of such investigations the more frequently will anomalies be found, but it does not follow that surgical treatment is indicated. It would be of great interest to know how many patients in this series were actually treated surgically and followed for, say, at least two years.—I am, etc.,

Diabetic Lipaemia

SIR,—The occurrence of diabetic lipaemia (milky plasma) was first described in the nineteenth century and remains a well-recognized but rare manifestation of uncontrolled diabetes mellitus.[1] Although prompt diagnosis and insulin treatment of diabetes mellitus have probably reduced the incidence of diabetic hyperlipaemia, reports of the condition still occur.[1 2] I wish to record a case of massive hyperlipaemia in a young diabetic who was thought to be reasonably well controlled with insulin therapy.

A 13-year-old boy was admitted to the Royal Devon and Exeter Hospital complaining of vomiting and severe abdominal pain for 24 hours. The boy was known to be a diabetic for three years before admission and was usually well controlled on 24 units lente insulin daily. On examination he had a tense abdomen but no masses were palpable. It was noted that he had a rapid respiratory rate and extreme difficulty in breathing. The white blood count was 30,000 cells/cu. mm., of which 83% were neutrophils. The blood sugar was 176 mg./100 ml., serum amylase was 160 Somogyi units/100 ml., serum sodium was 111 mEq/l., serum potassium was 3.1 mEq/l., serum chloride was 70 mEq/l., and bicarbonate 18 mEq/l. The serum was noted as being extremely milky in appearance. The urine contained glucose and a moderate amount of acetone.

Because of the uncertain diagnosis, laparotomy (Mr. C. Shaldon) was undertaken. At operation the stomach, jejunum, and bladder were dilated, but no cause was seen to account for these findings. A striking feature at laparotomy was the pink creamy consistency of the blood. After operation he was given 20 units soluble insulin three times daily and improved rapidly. Although the blood sugar was never apparently greater than 250 mg./100 ml., acetonuria persisted for a few days. After operation lipaemia retinalis was observed, but there were no microaneurysms or xanthomata. The plasma lipids were analysed on a preoperative specimen and on succeeding days. The results (Table) show a gross hyperlipaemia which gradually cleared. Since this time the boy has remained well and is receiving 36 units soluble insulin and 12 units protamine zinc insulin daily. Examination of the patient's parent's plasma has not shown any increase in the lipid content.

Day	Cholesterol (mg./100 ml.)	Total Serum Lipids (g./100 ml.)	Lipoprotein
0	1,350	14·9	Chylomicrons
3	508	3·4	Pre-β
5	540	2·4	β
6	490	1·76	β
9	—	1·14	—
19	—	1·56	—
3 months	186	0·9	β
6 ,,	113	0·6	—

Normal range—140–265 mg./100 ml. 0·34–0·9 g./100 ml.

The occurrence of massive hyperlipaemia in diabetes mellitus is described as a rare syndrome,[2] but was a more frequent observation in the era before insulin treatment of diabetes.[3] This case is unusual in that the boy had been well until 24 hours before admission, whereas other cases described have been preceded by a long period of illness.[1] It is probable that diabetic hyperlipaemia is an acquired but reversible form of fat-induced hyperlipaemia with subnormal post-heparin lipolytic activity and delayed removal of dietary fat.[1] The decreased activity of the enzyme appears to be secondary to hormone deficiency, which results in impaired synthesis of the enzyme in contrast to the inherited defect in enzyme synthesis seen in the familial disorder.

I should like to thank Dr. L. Haas and Mr. C. Shaldon, under whose care this patient was admitted, for permission to report this case.

—I am, etc.,

T. HARGREAVES.

Carcinogenic Properties of Ortho-dianisidine

SIR,—Dr. H. Lehmann's letter (19 August, p. 494) about the carcinogenic properties of ortho-tolidine (3:3′-dimethylbenzidine) and ortho-dianisidine (3:3′-dimethoxybenzidine) and his lament that in your leading article (22 July, p. 189) you do not give firm advice about whether these substances should be used or not in clinical routine practice raises an important question which at the moment cannot be answered in a simple and definite manner.

The Chester Beatty Research Institute has been asked from time to time to give guidance on this matter to individuals. The advice that has been given is as follows: While we believe that it is possible to handle these substances safely if adequate[1] precautions are taken, we think that suitable alternative methods should be sought, for sooner or later laboratory workers may become careless, and the dangerous substances must be manufactured, purified, and packed, possibly exposing other workers to a hazard.

Whether alternative techniques are satisfactory or not can often be assessed only in the framework of the duties of the laboratory concerned. However, the Association of Clinical Pathologists has already taken the initiative, and in a circular to its members[2] has asked biochemists who know of suitable alternative methods, particularly for techniques for the estimation of glucose by the glucose-oxidase method, to let the Association know. The leaflet gives a reference[3] to a bibliography of possibly useful tests for occult blood which are not based on carcinogens.

Some workers have informed me that they have changed to alternative techniques for glucose estimation—specific for glucose and not merely the estimation of reducing substances—which meet the needs of their particular laboratories.[4–6] Perhaps it would be helpful if details of their experiences with these methods were made available to biochemists, either through your columns or through the Association of Clinical Biochemists.

Similar problems have arisen in relation to the use of ortho-tolidine in tests for residual chlorine in water—in this case the Water Research Association has recommended an alternative test based on NN′diethylparaphenylene diamine, which is not believed to be carcinogenic—and in relation to the use of 1-naphthylamine in tests for nitrates in sewage effluents or in urine. Recently an alternative test for urinary nitrites has been proposed.[7] Here again it would be useful if the experience of those who have changed to alternative methods could be collated and brought to the notice of biochemists.

Since it is apparent that it will not be possible to abandon the use of all carcinogenic aromatic amines in medical biochemistry immediately, it would be wise in the meanwhile for the head of every laboratory where these substances are used to ensure that all his staff are aware of the possible dangers and of the necessary precautions, and to see that these precautions are in fact observed. —I am, etc.,

Transplacental Transmission of Herpes Simplex

SIR,—Gregg in 1941[1] and Swan and his associates[2] in 1943 first reported clinical observations on congenital anomalies in the offspring following maternal rubella. While Swan's observations were concerned chiefly with rubella, he postulated that other virus diseases in the mother might result in foetal maldevelopment.

Herpes simplex infection of the newborn may occur by transplacental transmission of the virus as well as by the more common mode of infection from active lesions in the birth canal.[3] Between 65% and 98% of adults will show neutralizing antibodies to the herpes simplex virus.[3] The incidence of herpetic lesion in the female genital tract is greater than generally recognized. Naib *et al.*[4] found that of approximately 40,000 indigent patients screened for cancer by routine "Pap" smear 62 (0.16%) had initial cytological evidence of a herpetic lesion. About one-third of these were pregnant. Because of these facts and because of the fact that herpes simplex virus in tissue culture causes a high percentage of chromosome aberrations,[5] it is plausible to suggest that herpes simplex cervicitis during early pregnancy may cause congenital malformations.

A 22-year-old primipara was admitted to the department of obstetrics and gynaecology at the General Hospital, Malmö, Sweden, on 23 June 1966 in labour. During the third month of pregnancy she was first seen in the outpatient service. At that time the labia majora were noticed to have several small ulcerations. The routine "Pap" smear showed initial cytological evidence of a herpetic lesion. The ulcerations healed spontaneously, and the pregnancy was uneventful until the 36th week of gestation, when the patient underwent a caesarean section because of toxaemia. The child was a phocomelus and died some hours after delivery because of respiratory distress. As far as we know the patient had not taken any medication during her pregnancy. From the age of 8 years she had been treated with insulin because of diabetes mellitus, which may give malformations, but as far as is known not of this kind.

The present congenital malformations and the maternal herpes simplex infection during early pregnancy may be coincidental. As no studies of a relationship appear to have been published, we hope that others may follow up cases with cytological evidence of herpetic lesions during early pregnancy, and report cases of foetal maldevelopment if any appear. —We are, etc.,

Snakebite Poisoning

SIR,—Dr. H. A. Reid (5 August, p. 367) has drawn attention to a newspaper report of snakebite which occurred in a local man.

At the time some concern was caused by the presence of local pain and tenderness, and of dilated pupils and weakness apparently not caused by fear alone, following injury by an unusual snake. This was later identified as a European grass-snake. For the future we have learned from the incident that antivenom is kept in the zoo concerned.

Needless to say, the drama of the occasion was considerably less than was depicted in the press.—I am, etc.,

CHRISTOPHER GARDNER-THORPE.

City General Hospital,
Stoke-on-Trent.

Ehlers-Danlos Syndrome

SIR,—Ehlers–Danlos syndrome may have a wide variety of manifestations. It is often difficult to be sure of the diagnosis, particularly in mildly affected individuals, since the microscopic anatomy is in "a disputed state," and the basic defect is unknown.[1] Thus Mr. A. P. Barabas's suggested clinical subdivision of cases (3 June, p. 612) is most helpful in elucidating the probable heterogeneity of the syndrome, and particularly in pointing out the existence of an "arterial" type which may cause fatal haemorrhage in early adult life.

As Mr. Barabas is aware, intracranial arterial aneurysm has been reported as a complication,[2] and one of us recently described three cases of spontaneous carotid-cavernous fistula in Ehlers–Danlos syndrome.[3] Two of the patients are siblings, a sister and brother, and the sister has since died after suffering a succession of further arterial complications. A brief report of this case may therefore be of interest.

She was last seen in 1961, aged 37, with a spontaneous left carotid cavernous fistula associated with remarkable ectasia of the left internal carotid artery, and alarming haemorrhage occurred at the time of carotid arteriography. Carotid ligation was performed, and one month after operation she developed small aneurysms of the left radial artery and the left superficial temporal artery. The latter disappeared spontaneously. These episodes and further complications occurring up to 1964 have been reported.[3] Her previous history included lifelong easy bruising and a myocardial infarction at the age of 35.

In 1965 she still had an aneurysm of the left radial artery, which was later excised at another hospital. In April 1967 the patient complained of weakness, fatigue, and fever, and then developed severe right-sided headache and blurring of vision in the right eye. On admission to hospital she showed right proptosis and third-nerve palsy, suggesting a right internal carotid aneurysm. Angiography was deferred because of the previous experience and because she also had many features of a systemic disease resembling polyarteritis nodosa. These included fever, hypertension, chest pain, weakness and extreme tenderness of limb muscles, leucocytosis, normochromic anaemia, and a very high sedimentation rate. Skin and muscle biopsy proved inconclusive, showing only slight perivascular infiltration, but a disturbance in the pattern of elastic fibres, in some parts loose and in others arranged in compact masses with a tendency to form nodules, was noted, compatible with the diagnosis of Ehlers–Danlos syndrome (Dr. Mario Montes).

She was treated with corticosteroids, and subjective improvement and disappearance of fever followed; vision improved in the right eye, and the proptosis and right third-nerve lesion both regressed. However, chest pain recurred and electrocardiographic evidence of a further anterior myocardial infarction was seen. Subsequently, a further aneurysm appeared on the right radial artery, the mirror image of that earlier excised on the left. Soon after, she suffered sudden acute swelling in the left calf with agonizing throbbing pain. This was thought to represent rupture of another aneurysm, and at operation, reluctantly undertaken, a false aneurysm was found arising from the left posterior tibial artery. Some 10 days later another aneurysm appeared on the right anterior tibial artery. Finally the patient complained of acute abdominal pain and became unconscious. Blood was aspirated from the peritoneal cavity but there was no time to attempt operation before she died. Necropsy showed that she had ruptured an aneurysm of the splenic artery; other aneurysms were found on mesenteric arteries. Polycystic disease of the kidneys and liver was also found.

It seems worth emphasizing that this patient had thin and unusually smooth skin, but it was not redundant or hyperelastic, and her joints were not unusually lax. As noted previously,[3] her brother had a similar left-sided carotid-cavernous fistula at the age of 30, but we are not aware that he has ever had other arterial complications, although we have not yet had an opportunity to examine him. A full study of the family is in progress; there is no other positive evidence of Ehlers–Danlos syndrome, although there are instances of subarachnoid haemorrhage and of unexplained deaths.

This case, which will be presented in detail, supports Mr. Barabas's contention that there may exist an "arterial" type of syndrome. It provides a particularly florid example, with a similar illness occurring in milder form in a brother. Although usually regarded as an autosomal dominant trait,[1] the possibility of different modes of inheritance in a heterogeneous syndrome has always to be considered, and one might speculate that some cases of the "arterial" form might be transmitted as autosomal recessives. If this were so parents would not be expected to show the trait, and absence of family history could be compatible with this mode of inheritance, as in the case of Rubinstein and Cohen,[2] another of our own,[3] and number 27 of Barabas.

The features of systemic illness (fever, etc.) in our patient are not well explained and it may be noteworthy that they had occurred in milder form earlier in this patient's history. We wonder whether others have had similar experiences and whether more acute episodes of arterial damage may occur in the course of Ehlers–Danlos syndrome.—We are, etc.,

Warning of Massive Pulmonary Embolism

SIR,—Dr. W. G. Smith (5 August, p. 370) rightly stresses the importance of early recognition and treatment of "warning" pulmonary embolus. This may not, however, be quite as usual as he suggests.

Coon and Coller[1] reported warning emboli in 25% of their cases of fatal pulmonary embolism, and Little, Lowenthal, and Mills[2] found that 7 of their 37 cases of fatal pulmonary embolism had evidence of warning embolus, an incidence of 19%.

A review of St. Thomas's Hospital records for the years 1959–64 shows a total of 76 cases of fatal pulmonary embolism. A definite warning embolus was recorded in 13 (17%) of these cases. In a further 16 cases symptoms of dyspnoea or chest pain were not considered sufficient for a definite diagnosis to be made, and in the remaining 47 cases sudden and profound collapse of the patient was apparently unheralded.

These figures suggest that massive fatal pulmonary embolism usually occurs without any warning. It is therefore all the more important to regard any symptom or sign of pulmonary embolus, however slight, as a potential "warning," and to treat it with the seriousness it deserves.—I am, etc.,

Chemical Treatment of Skin Cancer

SIR,—Your leading article (15 July, p. 125) on this subject made good sense. On several occasions I have witnessed Dr. Frederick Mohs at work in his clinic, and have been deeply impressed by both the logic of his chemosurgical method of therapy and the care with which he carries it out. The success he achieves in cases of advanced skin cancer and cases of cancer which have recurred after previous radiotherapy or surgery is unequalled by that attainable by any other method.

Dr. G. M. King (19 August, p. 495) states that his results from treatment with 5% 5-fluorouracil (5-FU) ointment, though it is much too early to assess the long-term success rate, have been "quite impressive." This statement can carry little weight, firstly because it is unsupported by figures which can be interpreted by others, and secondly because it is easy to obtain "quite impressive" results in the treatment of skin cancer by a wide variety of methods. The results would certainly have to be far more impressive than those obtained by E. Klein and his colleagues[1] with 20% 5-FU to justify the widespread adoption of this method of treatment. The possible value of 5-FU in the treatment of solar or arsenical keratoses is in my view a matter for separate evaluation. —I am, etc.,

Hazard from Nylon

SIR,—I was interested to read of the case of ischaemia of the finger-tip of a small infant reported by Dr. G. G. Noott (5 August, p. 370). A similar case came under my care not long ago in which a loop of fibre inside the baby's glove had strangulated the finger-tip, resulting in gangrene of the part.

This is a hazard I had not come across before, and it seems obvious that mitts made of material would be much safer than knitted gloves or mittens on tiny babies.—I am, etc.,

E. N. CALLUM.

Treatment of Mendelson's Syndrome

SIR,—Dr. G. Taylor's letter (5 August, p. 368) outlines a very comprehensive regimen of treatment when aspiration of gastric contents has occurred, and states that "vomiting and regurgitation of stomach contents . . . should be regarded as preventable." However, apart from the excellent recognition that all women in labour must be suspected of having a full stomach, irrespective of their last oral intake of food or drink, and the advice on giving oral antacids before anaesthesia, he omits emphasis of the use of various techniques available at induction of anaesthesia for prevention of inhalation of gastric contents. Presumably these are taken for granted, but in such an important subject, where prevention is considerably superior to cure, any mention of prevention (points (1) and (2)) should stress the importance of a well-organized technique of induction, maintenance, and termination of anaesthesia.

Several methods are available for induction of anaesthesia: varying the position of the patient, general anaesthetic agents used,[1-3] use of cricoid pressure,[4] or use of regional analgesia.[5-8]

No method can guarantee 100% safety, and, although we are grateful for any new methods of treating Mendelson's syndrome when it has occurred, we should strive our utmost to reduce the incidence of this complication by taking all possible steps to avoid its occurrence.—I am, etc.,

General Hospital,

Stewart–Morel Syndrome

SIR,—A woman, 77 years old, was admitted to our unit complaining of headache, vertigo, exertional dyspnoea, and some joint pains. It was noted that she exhibited hirsutism, and she told us that it has been necessary for her to shave each day for about 20 years. She did not remember when she started menstruation, but her periods were regular and she had had the menopause at about the age of 45 years.

On examination there was pallor, slight pitting oedema of both ankles, and lipomatosis of both arms and thighs. Her blood pressure was 220/

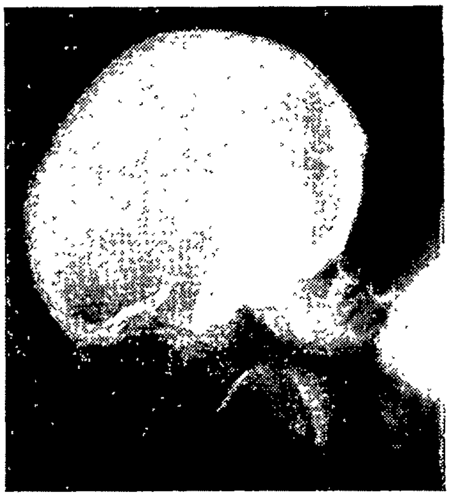

FIG. 1

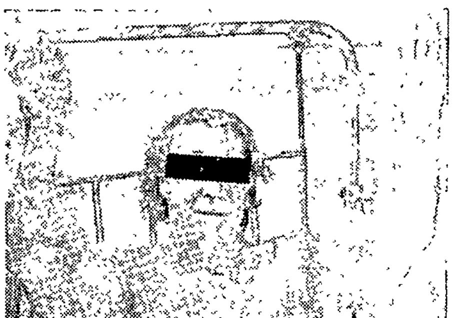

FIG. 2

110 mm. Hg. She was confused with paranoid trends and exhibited hallucinations at times. Depression had also been noted by her relatives before she was admitted to hospital.

Physical examination showed osteoarthritis of both knee joints and small joints of the hands, confirmed by *x*-ray. Intravenous pyelogram showed normal appearance of both kidneys. Her haemoglobin was 6 g./100 ml. and the blood picture was hypochromic and microcytic, which improved after iron therapy. Blood sugar, electrolytes, proteins, and cholesterol were normal. There was no glycosuria, and urinary 17-ketosteroid estimation was within normal limits. *X*-ray of the skull showed well-marked hyperostosis frontalis interna (Fig. 1). As seen in Figs. 2 and 3, obesity was mainly limited to the upper arms and thighs.

Association of hirsutism, obesity, and hyperostosis frontalis interna has been observed under the title of "Stewart–Morel Syndrome" or "Morgagni–Morel Syndrome." Morel reported 17 cases and Stewart reported a few cases.[1] Michaux described a case in 1959 presenting mental symptoms along with this syndrome.[2] Aubertin described a patient with arterial hypertension.[3] All say that the case is obscure. The newly formed bone is deposited in the inner aspect of the frontal bones with considerable thickening—resulting in atrophy of frontal lobes and pituitary dysfunction—and has almost always been recorded in women.

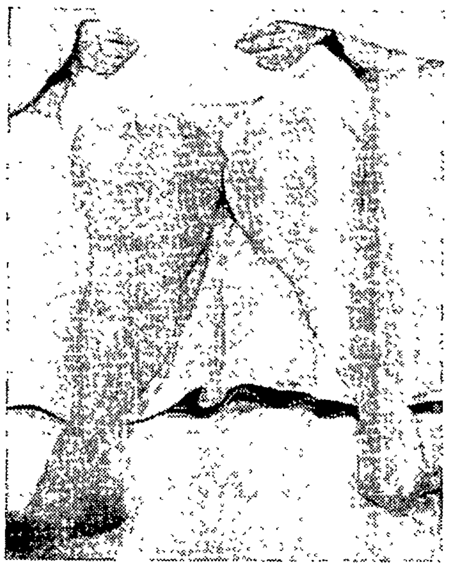

FIG. 3

Our patient presented all features of the syndrome—that is, hyperostosis frontalis interna, hirsutism, obesity, mental and nervous symptoms, and hypertension.—We are, etc.,

Hypogammaglobulinaemia in Adults

SIR,—Your special correspondent's account of my lecture on hypogammaglobulinaemia in adults (5 August, p. 362), given at the conference on disorders of protein metabolism at the Royal College of Physicians, London, contains some misquotations.

Hypogammaglobulinaemia in adults is of two types: primary, in which the deficiency of gammaglobulin is of unknown origin, and secondary, in which it is due to protein loss from the gut or kidneys or results from the effect of neoplasms upon immunoglobulin production. I did not say that the disease could be due to the toxic effects of drugs, and there is no evidence that hypogammaglobulinaemia can be caused in this way.

The eighteen patients whom I reported had all been diagnosed as having hypogammaglobulinaemia in adult life. The onset of the disease as judged by the history of recurrent infections was not, as stated in your report, always in adult life. In four of these adults the first onset of recurrent infections had occurred in childhood.—I am, etc.,

Cardiac Resuscitation

SIR,—As a lecturer and examiner in first aid for both Red Cross and St. John Ambulance Societies over the past nine years, I can substantiate Dr. J. D. Barrett's feelings (12 August, p. 437) that the indications for external cardiac compression are not understood by the majority of first-aiders who have only attended one or two courses. Often candidates state at examination that if the casualty does not respond by spontaneous breathing after the first four to six inflations of the lungs then external cardiac compression should be started. There is no thought of palpating the neck for pulsation, of observing the colour of the lips, or of noting the condition of the pupils. I feel that many casualties would be better with only basic first aid—that is, arrest of haemorrhage, ventilation of the lungs, and the treatment of cuts, burns, and fractures. I suggest that external cardiac compression should be taught to recognized "life-savers" who have passed at least two first-aid examinations and have shown aptitude in diagnosis, and not to those who have only just started.—I am, etc.,

Insulinotropic Action of Secretin

SIR,—Drs. D. R. Boyns, R. J. Jarrett, and H. Keen (10 June, p. 676) have confirmed the insulin releasing action of secretin in man but report evidence which they suggest throws doubt on the possible physiological role of this hormone in the regulation of insulin secretion. Some of our observations in studies related to this question and in studies of the effects of pancreozymin are at variance with theirs. In the earlier experiments of Boyns, Jarrett, and Keen with intraduodenal infusions of citric acid hypertonic solutions of glucose were delivered into the duodenum as a means of raising the blood glucose concentration.[1] With this procedure possible effects of the hypertonic solution on secretin release might obscure further effects of acidification of the mucosa. However, it is clear from the results of the three experiments reported in their recent paper that the infusion of 2.5 mEq of citric acid into the duodenum did not significantly modify the response to intravenous infusion of glucose.

We are in the course of a series of experiments in which hydrochloric acid is infused in the duodenum for a period of 20–40 minutes to a total dose of 30 mEq while glucose is given intravenously. This dose of acid does not exceed estimates of the normal acid secretion in response to a mixed meal.[2] In two out of three experiments distinctly higher levels of serum immunoreactive insulin were observed while the acid was infused into the duodenum; and in the third a difference in the same direction was recorded. Moreover, we have found that the intravenous infusion of synthetic human gastrin in six normal subjects modifies the response to intravenous glucose in the same manner as secretin, and it seems that this effect may be mediated by stimulation of acid secretion.

Our findings with a highly purified preparation of pancreozymin of verified exocrine activity differ from those of Boyns, Jarrett, and Keen. This preparation administered to eight subjects in doses of 25 to 50 μg. has consistently enhanced the rise in serum insulin associated with intravenous infusion of glucose and has accelerated glucose disposal. In fasting subjects little or no change in peripheral serum immunoreactive insulin is obtained when pancreozymin is administered intravenously, but a large transient rise in portal serum immunoreactive insulin has been observed. The same preparation of pancreozymin enhanced the change in serum insulin concentration associated with intravenous infusion of arginine in eight normal subjects. We believe that all preparations of secretin or pancreozymin must be tested for exocrine activity after use in experiments yielding negative results. Our findings will be presented at the forthcoming meeting of the International Diabetes Federation.

It is unlikely that duodenal infusion of isotonic glucose causes secretion of pancreozymin in man, and it has been shown by Dr. R. Preshaw at McGill[3] that such infusions do not produce exocrine effects of secretin in man. This procedure was used by McIntyre and his colleagues[4] to demonstrate enhanced insulin secretion in man during intestinal absorption of glucose. It appears, therefore, that an insulinotropic hormone other than secretin or pancreozymin is secreted when glucose is absorbed from the small intestine. However, the response to ingestion of protein together with carbohydrate suggests to us that stimulation of the endocrine pancreas is further potentiated to an extent not fully accounted for by the direct effect of circulating nutrients. The digestive secretagogues may be responsible for this potentiation.—We are, etc.,

Mortality of the Ambulance Ride

SIR,—The letter from Mr. C. H. Cullen and others (12 August, p. 438) inadvertently underlines the great importance of taking seriously injured patients to the proper centre even if it does mean a rather longer ambulance journey initially. Only in this way can the problem Mr. Cullen pinpoints be avoided. It is no use resuscitating a patient if he then has to travel to receive the necessary subsequent treatment. And, far from relating only to transfers between hospitals, this applies with great force within the hospital in the siting of *x*-ray departments and operating theatres in relation to the resuscitation room.

Those who have much experience of accident surgery know that in the critical phase, when a patient has just been resuscitated sufficiently for the anaesthetist to dare accept him for surgery, he must be transferred to the theatre *on tiptoe*. Trundling such a patient along a hundred yards of corridor will do the same as the ambulance journey did to Mr. Cullen's patient. A journey on a trolley stationary in a lift, however many floors are traversed, will affect him far less.

The place for resuscitation is the place which can supply the whole treatment. Staging patients for resuscitation en route can only increase the mortality.—I am, etc.,

Canterbury. F. G. St. Clair Strange.

Fulminating Ulcerative Colitis

Sir,—I must take issue with your correspondent Mr. T. A. Boxall (5 August, p. 368).

In the large majority of cases Professor Goligher and his team carried out a total proctocolectomy and not simply a subtotal colectomy (22 July, p. 193), although your leading article in that issue perhaps tended towards the less radical view.

Any surgeon who has had the experience of dealing with a rectal remnant which has continued to bleed severely, to perforate and to form abscesses and massive adhesions to bladder, urethra, and small intestine—requiring a second operation of great technical difficulty and severity—must surely hesitate to leave behind the rectum at the primary operation unless it can be clearly shown to be not more than slightly diseased.—I am, etc.,

Glasgow. D. M. Sinclair.

Casualty Department—or G.P. Service?

Sir,—Mr. R. S. Murley (22 July, p. 245) rightly criticizes your previous correspondents' (1 July, p. 46) defeatist attitude to the abuse of the hospital casualty service. This abuse is not only typical of the larger city centres but is becoming increasingly common in smaller hospitals serving a "well-registered" population since more and more general practitioners are adopting appointment systems. "I can't get an appointment at the surgery till Wednesday" is a familiar excuse to many a casualty officer on Monday mornings.

I would not agree, however, that the doctors' efforts to educate the public are "largely doomed to failure." Much can be done if the casualty staff are prepared to establish the department's reputation locally as a place where only genuine emergencies will receive attention. This entails close co-operation with the general practitioners, asking them to be firm with their patients who attend unnecessarily, making sure that local works first-aid personnel know this attitude, and so on.

Because casualty work is not recognized as a specialty in its own right, this venture may prove difficult. Support at management committee and medical staff committee levels is often lacking, and much of the out-of-hours work may be done by junior doctors from other departments who have no enthusiasm to help solve a problem which is not theirs to begin with. Only the creation of a proper career structure in this work will give casualty departments the type of staff they need to function to their best advantage and eliminate this abuse.—I am, etc.,

Stockton-on-Tees. J. H. Jennings.

Health of Students and Soldiers

Sir,—I would entirely agree with Colonel H. G. Skinner's comments on planning a health service (15 July, p. 178).

Some 15 years ago, when I was a postgraduate student at the London School of Hygiene and Tropical Medicine, I attended an elective course of lectures on what was to me a new subject—"Industrial Psychology." As the content of the course unfolded, it was interesting to note that we were covering the principles of man-management which had earlier been instilled into me as a very junior regimental medical officer by the more senior regimental officers of the battalion in which I was privileged to serve.—I am, etc.,

Eastern Command,
Hounslow, Middx. F. G. Neild.

Consultants' Views of G.P.

Sir,—Perhaps one should not take too seriously remarks made in the heat of debate, but some words ascribed to Dr. B. D. Morgan Williams (*Supplement*, 12 August, p. 115) call for comment.

He is reported as saying that "Teaching-hospital consultants saw only the worst side of general practice: they did not see the successes." I should like to record that in my own experience this is complete nonsense. Neither in private practice nor in outpatient clinics did I see only the worst side of general practice, and I cannot believe that my experience was unique. This kind of remark is to be deplored, and I feel someone ought to say so.—I am, etc.,

London, N.1. Cecil Flemming.

Radio Communication and the G.P.

Sir,—Referring to the letter from Dr. K. A. Harden, of Glasgow (5 August, p. 374), in this practice we do indeed have an arrangement whereby the hospital can hear our report radioed direct from the car.

This is done through a commercial organization—Air Call, of Hitchin—who on receipt of our message contacts the hospital by telephone, and by leaving the switch open in the control office allows the hospital doctor to hear our message. This saves many a letter in the wee small hours, and we can vouch for the great saving in time.—We are, etc.,

B.M.A. Department of Audio-visual Communication

Sir,—The pressure of urgent business at the Annual Representative Meeting at Bristol prevented me from presenting the report of the Film Committee and informing members about the future plans of the Association's new department of audio-visual communication. Briefly, for the immediate future, these are:

(1) To hold a three-day founding conference entitled "Educational Technology in Further Medical Education" at the University of Sussex on 3, 4, and 5 January 1968. (Full details will be published early this autumn.)

(2) To create an advisory service covering the content, availability, and suitability of audio-visual source material of all kinds and the advantages and disadvantages of recording and presentational apparatus in all media.

(3) To serve as a co-ordinating centre for individual effort in the whole field of audio-visual communication in medicine.

(4) To upgrade and recatalogue the present film library and to enlarge the library of audio tapes in order to increase its usefulness to doctors and others both at home and abroad. (Modern apparatus for the servicing of films returned by borrowers has now been installed.)

(5) To promote the making of clinical and health education films by bringing together medical men with ideas, film makers, and potential sponsors and to encourage the setting up of trust funds to sponsor specific projects.

Eventually it is hoped that a hallmarking system for medical films can be introduced which will enable a prospective user to identify titles whose professional and ethical standards are acceptable to the Association. The provision of training courses for medical teachers in the use of apparatus appropriate to the newer media of communication is also under consideration.

I am also happy to report that shooting has actually started on a film dealing with the problem of juvenile obesity that is being sponsored jointly with the British Life Assurance Trust. The newly appointed head of department, Mr. Charles Engel, will be taking up his duties in September.—I am, etc.,

Points from Letters

Aversion Therapy of Homosexuals

Dr. C. E. Allen (Mold, Flintshire) writes: It is unfortunate that Dr. B. Kalcev (12 August, p. 436) claims that homosexuality is not a disease, because the dictionaries I have consulted suggest that a disease is merely an abnormal condition. The fact that it has a psychological basis does not make it any less a disease.

This is not to suggest that I feel that treatment should be forced on those who do not wish it. Since I have treated a very large number of homosexuals I know that anyone who tries to treat a patient who does not wish it is wasting his time. It should be appreciated that homosexuality leads to unhappiness. The homosexual is never able to fit comfortably into a society adjusted for heterosexuality. He is often unhappy during his youth because he feels different from others, and when old age comes is intolerably lonely. For these facts alone it is worth urging him to accept treatment, and, if he can respond, to be cured.

Obituary Notices

LEON GILLIS, M.B.E., M.CH.ORTH., F.R.C.S., F.R.C.S.ED., D.L.O.

Mr. L. Gillis, consultant orthopaedic surgeon in the Westminster Hospital Teaching Group at Queen Mary's Hospital, Roehampton, died at Birmingham, Alabama, U.S.A., on 9 August following an operation.

Leon Gillis was born in Johannesburg on 4 September 1908. He qualified in medicine at the University of Witwatersrand in 1935, and came to England in the following year. He took the M.Ch.Orth. at Liverpool in 1937, the Edinburgh Fellowship in 1942, and the English Fellowship in 1945; but before settling down to his chosen specialty he worked for a time in oto-laryngology, taking the D.L.O. (London) in 1940. He held a number of hospital appointments in and around Liverpool and later at the Borough General Hospital, Ipswich, before being appointed consultant orthopaedic surgeon at Queen Mary's, Roehampton, in 1943.

It was at Roehampton that his great work was done. Successive echelons of ex-Servicemen, both amputees and those suffering from the various sequelae of gunshot wounds of the extremities, owed their rehabilitation to his skill.

It was his special thesis that amputation and limb-fitting are parts of one operation, and he spoke and wrote endlessly to get this principle accepted throughout the country. Few had a wider knowledge than he of the problems of the amputee, and his two books on the subject—*Amputations*, published in 1945, and *Artificial Limbs* (1947)—became standard works. He had also an unrivalled knowledge of congenital limb deformities, including those due to thalidomide, and made special contributions to their management in the children's prosthetic unit at Roehampton. His opinion and advice on special problems in amputation and limb-fitting were sought by orthopaedic, vascular, and general surgeons all over England and from overseas. His achievements gained wide recognition, including appointment to the Arris and Gale lectureship in 1948, a Hunterian professorship in 1956, and the Joseph Henry Memorial lectureship in 1960. In 1947 he was honoured by the award of the M.B.E.

Leon extracted an unbelievable amount of working time out of every 24 hours. In addition to his work at Roehampton he was until 1961 consultant orthopaedic surgeon to the East Ham Memorial Hospital, Barking Hospital, and St. John's Hospital, Battersea. He was also consultant to the Ministry of Health's Limb-fitting Centre at Roehampton and surgical adviser to the Treasury. A long succession of registrars found him an erudite and stimulating teacher, and his biannual postgraduate courses were in great demand both from consultants and from candidates for the Fellowship. He wrote prolifically, contributing chapters to at least 10 major textbooks and publishing nearly 40 papers on a wide variety of subjects in medical and nursing journals. Somehow he found time, too, to serve on two hospital management committees and on the Orthopaedic Advisory Committee of the North-east Metropolitan Regional Hospital Board.

In his last years he was increasingly restricted by ill-health, but he fought most gallantly against it. His death followed an operation which he bravely and clear-sightedly accepted as a gamble that might not come off. He is survived by his wife and by two sisters.—A. G. R.

Colonel E. E. S. WHEATLEY C.B.E.(MIL.), D.F.C., T.D., M.R.C.S. L.R.C.P.

Colonel E. E. S. Wheatley, who died on 22 June at Kingston Hospital, combined several lives in one normal span and led a varied and exciting life as soldier and doctor.

Edward Eric Spencer Wheatley was born in India on 29 October 1898, the youngest son of Colonel Henry S. Wheatley and grandson of Major-General Wheatley, of the Bengal Cavalry. He was educated at Wellington College and the Royal Military Academy, Woolwich, whence he passed out second in his year, having also played rugby for the Military Academy. Commissioned in the Royal Artillery while still under the age of 18, he was almost immediately seconded to the new Royal Flying Corps. He served in France, Salonika, and North Russia and for his valour was awarded the D.F.C. He was shot down in Salonika while acting as observer, sustaining a severe injury to his right leg. This troubled him gravely for the next 30 years and left him with chronic osteomyelitis of the tibia. In 1946 he came back from Singapore and entered Millbank for an above-knee amputation.

Meantime, after the 1914–18 war, he rejoined his regiment, the Mountain Battery, Royal Artillery, in India. During his service there, in spite of the chronic osteomyelitis of his right leg, he boxed for the Army and acted for a period as A.D.C. to the Viceroy. On his return to England he transferred to the Army Pay Corps, qualifying as Paymaster, Aldershot Command.

In 1927, at the time of the "Geddes Axe," he decided to leave the Army and to study medicine. This he did at St. Thomas's Hospital, qualifying with the Conjoint diploma in 1932. He settled in Reading in general practice and did a good deal of surgery in addition. Joining the Territorial Army he raised No. 6 Motor Ambulance Column, which he took to France at the outbreak of the war in 1939. He later commanded No. 6 C.C.S. The next major move in this unusual life was Wheatley's mobilization of the 69th British General Hospital, which he commanded in the 1st Army landing in North Africa. After serving with the Central Mediterranean Forces until the end of the war he went to Singapore as A.D.M.S. Wheatley was decorated C.B.E. for his outstanding work and leadership in face of continual physical suffering. After the amputation of his leg he entered the Ministry of Pensions Artificial Limb Service, at Roehampton, in 1948. He continued to serve at Roehampton until 1963, when he retired.

A colleague writes: Kerry Wheatley was an outstanding soldier and doctor. We in the Limb Service who came to know and love him were gradually aware that his extraordinary ability for caring for the limbless derived from the various careers that had followed one another, logically, throughout his life. His knowledge of engineering learned at the Shop, his deep understanding of the life of the serving soldier and airman, his thirty years of suffering with a Great War wound, his leadership and command—these experiences trained him in a unique way for the unstinted service he lavished on his fellow amputees throughout the last fifteen years of his life. Thousands of those who have lost limbs as Servicemen or as civilians have reason to bless him for his knowledge and his practical sympathy. To see the tenderness with which he ministered to a maimed child was a benison given only to those who worked with him. He will not easily be forgotten at Roehampton.

J. CALDWELL, M.D.

Dr. J. Caldwell, a general practitioner in Paisley, died suddenly on 22 July while on holiday at Onich, near Fort William. He was 68.

James Caldwell was born in Paisley on 22 May 1899, and was educated at Paisley Grammar School and Glasgow Academy. During the first world war he served in France as a subaltern in the Argyll and Sutherland Highlanders. After demobilization he studied at Glasgow University, where he graduated M.B., Ch.B. in 1924 and proceeded M.D. in 1947. Following house appointments at the Royal Alexandra Infirmary, where he was senior medical resident, he visited the United States and spent some time at the Mayo Clinic. On his return he set up practice in his native town of Paisley, where he served the community as a general practitioner for 40 years. The care of the aged was a particular interest of his, and until three years ago he was active in the field of geriatrics. He was visiting physician to Glen-Coats Auxiliary Hospital from 1934 until 1962, when he was appointed to take charge of the new geriatric unit at Barshaw

Hospital. He was a representative at the Annual Meetings of the British Medical Association from 1930 to 1936, and again in 1938, and was chairman of the Renfrew and Bute Division from 1957 to 1959.

James Caldwell was a kindly, good-hearted man with a genuine interest in the well-being of his patients, many of whom regarded him as a personal friend as well as a beloved family doctor. Extremely fond of children, and with a boyish sense of fun, he made his visits memorable and welcome events to the younger members of the household, with whom he had endless patience. His clinical approach was always painstaking and scrupulously correct, and, although he kept well abreast of modern methods and treatment, he would on occasion take great delight in using, with effect, an old-fashioned remedy when more modern therapeutic agents had failed.

His pleasures were simple, and consisted mainly in his garden and conservatory, and the possession of a fine stamp collection. While devoted to his work, James Caldwell was also a very sociable man, and made a charming and interesting companion. He will be sadly missed by his many friends. He was a bachelor.—J. L. H.

G. R. CUBITT, T.D., M.B., B.CH., B.A.O., D.OBST.R.C.O.G., L.M.

Dr. G. R. Cubitt, a general practitioner in Sleaford, Lincolnshire, died on 24 July after a short illness. He was 54.

George Roland Cubitt was born in Waterville, Co. Kerry, on 16 October 1912, and was educated at the Farren Ferris College, after which he entered University College, Cork, graduating M.B., B.Ch., B.A.O. in 1938. He held resident posts in London before joining the R.A.M.C. in 1940. He served at home and in Europe during the second world war, and was deputy assistant director of medical services at the headquarters of the 30 Corps district, B.A.O.R., attaining the rank of major. On demobilization in 1945 he spent six months at the Rotunda Hospital, Dublin, and obtained the L.M. in 1946. He entered general practice in Sleaford the following year. It was largely due to his initiative that the Sleaford general practitioners joined together to form the Sleaford Medical Group, and designed their own health centre, which has proved an outstanding success in the district. In 1956 he took the diploma of the Royal College of Obstetricians and Gynaecologists from general practice. He was a devoted general practitioner, and also had many wide interests. He served as chairman of the Kesteven Division of the British Medical Association in 1954–5, and later was active in the affairs of the College of General Practitioners. He had been for many years a member of the Kesteven local medical committee. In addition, he was area commissioner of the St. John Ambulance Brigade, and a Rotarian, as well as a leading member of the Roman Catholic community. He never lost his interest in the Army, and was a keen Territorial. For his services he was awarded the Territorial Decoration. At the time of his death he was in command of 222 Field Dressing Station, R.A.M.C. (V.), with the rank of lieutenant-colonel.

Roland was an outstanding doctor, and one of the leading figures in medicine in the south of Lincolnshire, and his advice was sought by many, both in general practice and in the hospital and public health services. He had strong views of the duties of a general practitioner, and never spared himself. His pleasant personality made him very many friends, and he enjoyed their company. He was an ideal host, and many people will remember the happy evenings spent in his home. His death will leave a gap in the medical and public life of Sleaford, and also in a very wide area around.

Despite his many commitments, he enjoyed an ideally happy family life, and our sympathy is extended to his widow and three children.—A. A. H. and H. A. C.

G. R. MALKIN, M.R.C.S., L.R.C.P.

Dr. G. R. Malkin, formerly in general practice at Fownhope, Herefordshire, died at his home at Dawlish, Devon, on 6 August, after a long illness courageously and patiently borne. He was 67.

Godfrey Reginald Malkin was born in Staffordshire on 27 June 1900, and he received his medical education at St. Bartholomew's Hospital, London, where he qualified with the Conjoint diploma in 1930.

After various appointments he worked for a time in Worcestershire, and in 1939 he finally settled in general practice at Fownhope, Herefordshire, where he remained until his retirement in December 1965. He had in addition an extensive country practice which entailed a good deal of walking and rough travelling. Nevertheless, he found time to be honorary anaesthetist to the General Hospital, Hereford, until 1948, and during the second world war looked after the children at Brockhampton Court and an emergency hospital at Woolhope. After 1948 he found time to undertake the training of trainee assistants, and launched a whole series of young doctors on their life's work. Dr. Malkin was an extremely kind, patient, and capable physician, rightly beloved by his patients and neighbours. He had a deep interest in archaeology, entomology, and photography, and was a member of the Woolhope Club. For many years chairman of Fownhope Parish Council, he helped the village with its post-war building and reorganization. Interested in model-making, he had a wonderful workshop, and invented and made numerous models and gadgets which he used round his home.

We extend our heartfelt condolences and sympathy to his wife and family.—G. B. McM.

G. W. writes: With the death of Godfrey Malkin the profession in Herefordshire has lost a member of the type for which the county is noted—a first-class single-handed country doctor. He was an ideal man to act as a trainer, and seven of us passed through his capable hands. We are ever in his debt for the grounding he gave us in good general practice and the high example he himself set in his skill and humanity in dealing with all his patients, from landed gentry to gipsies. The esteem in which he was held was shown on his retirement, when, on a moving occasion in the village hall, he was presented with a large cheque and, something he prized much more, an inscribed list of the three hundred families who had contributed. Alas, his retirement, which he had planned to fill with his many interests, was ended after only two years by a painful illness borne with great courage. Having lived in his home for two years and known the happy family life he enjoyed so much, I know how much his loss will be felt by his wife and daughter.

S. W. MASLEN-JONES, M.S., F.R.C.S., F.R.C.O.G.

Mr. J. C. Newbold writes: Samuel Maslen-Jones (obituary, 5 August, p. 375) was a singular man, and lived a singular life in that he spent most of it serving a small special hospital. There are only a very few hospitals which deal with both obstetrics and gynaecology but nothing else, and the Women's Hospital, Wolverhampton, is such a hospital. Needless to say, this type of hospital cannot be matched for the training of specialists in obstetrics and gynaecology, and many men throughout the British Isles, and all over the world, can bear witness to this fact. With all the obstetrical and gynaecological abnormalities from a population of half a million under one roof a rare feast of clinical and teaching material is presented, and Maslen saw to it that each of his registrars and housemen left the hospital full of knowledge and very well trained. It was his custom to eat lunch with his residents, an even better place to teach than the bedside. There will be many reading this who owe Maslen a great personal debt, and I am sure they would wish me to express their gratitude to him.

As his colleague, it is not possible to speak of his character save in superlatives, which he would not have wished me to do. I can best illustrate the sort of man he was by the following stories from his life. When he first came to Wolverhampton the "Women's" was an individual hospital, and Maslen was responsible only to a lay committee. Within a few weeks he was "on the mat" because a patient had died—of which the committee disapproved. No radical surgery to extirpate cancer had ever been done before, and no risks had been taken. Maslen explained that it would be his policy to endeavour to cure women, whatever was wrong with them, and that, if the committee did not approve, they could have his resignation. He had no further trouble.

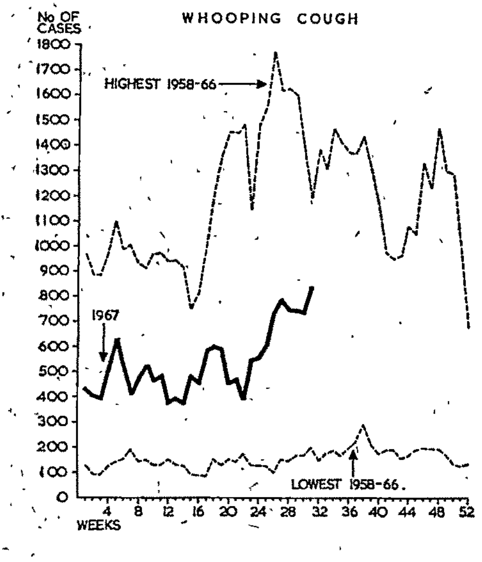
In conclusion, I must give an account of our first social meeting. Characteristically, this was an invitation to play golf. At one hole, which proceeded over the brow of a hill, the line was marked by a direction post. My ball was far and wide, but Maslen's, as usual, was absolutely straight and 50 yards short of the post. He asked me to walk ahead and remove the post. For a moment I suspected him of psychological warfare, but, being in no position to refuse, I walked on and took out the post. A well-struck iron soared exactly over the post-hole and would undoubtedly have hit the post had it remained in situ. And so he lived his life: straight, predictable, confident, skilful, unostentatious.

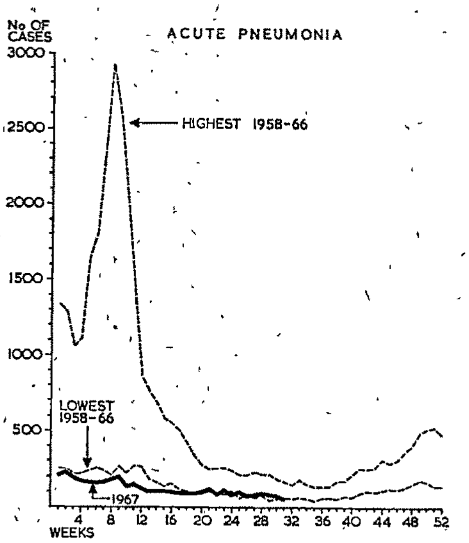
News and Notes

EPIDEMIOLOGY

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of whooping-cough and acute pneumonia in England and Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown





Infectious Diseases

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **5 August** (No. 31) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

MEDICAL NEWS

Technology in Medical Education

The place of educational technology in continuing medical education will be the theme of a founding conference for the new British Medical Association Department of Audio-visual Communications which is to be held from 3 to 5 January 1968 at the University of Sussex. The purpose of the conference is (*a*) to help medical teachers to become familiar with the contribution that educational technology can make; (*b*) to provide an opportunity for the exchange of views on the future development of the department; and (*c*) to introduce the head of the department, Mr. Charles Engel (see *B.M.J.*, 13 May, p. 453). A letter about the new department appears at p. 561.

Fire Hazards in Hyperbaric Treatment

A working party set up by the Western Regional Hospital Board (Scotland) concludes that the fire risks associated with hyperbaric treatment are sufficient to justify prompt action and continuing surveillance. In its report it makes a number of suggestions, including investigation of the risks in hospital wards where oxygen tents or oxygen incubators are used. The working party, which visited hyperbaric installations at Glasgow hospitals, does not consider that the hazards, if controlled in accordance with its recommendations, are grave enough to require curtailment of treatment in hyperbaric environments.

Benefits for Pneumoconiosis

New regulations affecting entitlement to benefits under the Industrial Injuries Act for pneumoconiosis came into operation on 16 August. They provide that the effects of emphysema or chronic bronchitis shall be treated as if they were the effects of pneumoconiosis in cases where disablement from pneumoconiosis or pneumoconiosis accompanied by tuberculosis would, if the person's physical condition were otherwise normal, be assessed at not less than 50%. The regulations apply to disablement benefit and industrial death benefit.

Providing Access for the Disabled

A new B.S.I. code of practice (C.P. 96) details general provisions that should be incorporated in new buildings for the convenience of the physically handicapped (see leader at p. 510). Copies of the code, *Access for the Disabled to Buildings, Part 1, General Recommendations,* can be obtained from B.S.I. Sales Office, 101–113 Pentonville Road, London N.1, price 10s. (plus 6d. postage to non-subscribers). Other parts of the code will cover specific building types.

Hospital Inpatients

Several new tables have been introduced into the Report on Hospital Inpatients Inquiry for 1963, Part 1, issued by the Ministry of Health and the General Register Office (H.M.S.O., £1 11s.). One of these shows the mean duration of stay in hospital for each diagnostic group by age, sex, and marital status; another, the patients treated in each hospital group according to their local authority area of residence. For the first time periods of preconvalescent care have been included in the duration of stay calculations. The report consists of detailed tables similar to those published in the corresponding volume for the preceding year.

R.C.S.I. Faculty of Radiology

The following officers have been elected: *dean,* Dr. O. Chance; *vice-dean,* Dr. W. J. MacHugh; *secretary,* Dr. D. Cantwell; *treasurer,* Dr. J. J. Magner.

Research on Air Pollution

A five-year programme of research on air pollution is to be undertaken at the Atomic Energy Research Establishment, Harwell, at an estimated cost of £535,000. It will aim at establishing the scientific facts required for an improved system of control. In an announcement last week the United Kingdom Atomic Energy Authority said the national cost of air pollution had been assessed at over £350m. a year, including costs of cleaning and damage to buildings. The chief pollutants had been smoke, dust, grit, and oxides of sulphur, but the greater use of oil fuels was increasing the amount of hydrocarbons, carbon monoxide, oxides of nitrogen, lead, and vanadium in the atmosphere. Harwell's main contribution is expected to be in analytical instruments and techniques, in studies of pollutant life cycles and reactions, and possibly in research on human inhalation. The work will be co-ordinated with other public research by Dr. Cecil Hall, director of the Warren Spring Laboratory of the Ministry of Technology.

Landscape Architecture for Hospitals

Practical advice to hospital planners and builders in making use of the natural resources of their sites is provided in a King's Fund report (*Landscape Architecture for New Hospitals,* 17s. 6d. post free). The author, Mr. J. Bodfan Gruffydd, was appointed by the fund in 1964 to advise on the layout and upkeep of hospital grounds (see *B.M.J.*, 1964, 25 July, p. 258). His report is wide-ranging and includes a section on design principles of therapeutic significance. There are 53 illustrations.

I.F.M.S.A. General Assembly

The sixteenth general assembly of the International Federation of Medical Student Associations was held from 1 to 12 August in Vienna. Delegates from nearly 30 countries were present. Among the British delegates were Mr. Cliff Allen, president of the British Medical Students' Association, and Mr. Michael Simpson, vice-president. The next general assembly will be held in Helsinki in 1968.

United Hospitals Choir

Since it was formed in 1951 the United Hospitals Choir has been giving regular concerts and recitals in London in aid of medical charities. Anyone may join who is connected with medical work. There is no audition. Rehearsals are held on Thursday from 7.30 to 9.45 p.m. at St. James's and St. Peter's School, Piccadilly. The autumn term starts on 28 September. There are vacancies in all voices. Further details can be obtained from the Honorary Secretary, Miss F. J. Allatt, 23 Guernsey Grove, London S.E.24 (telephone 674 6765).

Eli Lilly Fellowship (South Africa)

Medical practitioners registered in South Africa are invited to apply for the 1968 award of the Eli Lilly Medical Research Fellowship (South Africa). Details can be obtained from Dr. H. A. Shapiro, Chairman, Selection Committee, Eli Lilly Medical Research Fellowship (South Africa), P.O. Box 1010, Johannesburg, South Africa. The closing date for applications is 14 February 1968.

Clothing for the Disabled

Lack of communication within hospitals and between manufacturers and users is a main finding in a recent survey report on problems of clothing for the sick and disabled. The report recommends that an information centre should be established, also some form of regular publication, for the use of disabled persons in every environment and of relatives and professional staff. It also makes recommendations about the supply of suitable garments and their maintenance. Copies of the report can be obtained from the Disabled Living Activities Group, Central Council for the Disabled, 39 Victoria Street, London S.W.1, 10s. 6d. post free.

People in the News

▶ Dr. A. Isabel Scott has been appointed medical director to the National Drugs Advisory Board in Eire.

▶ Mr. A. G. Shaw, F.P.S., has been appointed secretary of the Association of the British Pharmaceutical Industry with effect from 1 November.

▶ Mr. James Loring has been appointed director of the Spastics Society.

News in Brief

The Minister of Health has agreed that the Liverpool Stanley Hospital, Liverpool 5, should continue to function for the time being. From 1970 there will be an annual review of the hospital facilities in that part of Liverpool, the final closure of the hospital being linked with the commissioning of the second phase of the new hospital at Fazakerley.

An exhibition of medical illustration, mainly anatomical and pathological, has been arranged at the Royal College of Physicians of London (11 St. Andrew's Place, London N.W.1). It is open from 10 a.m. to 5 p.m., Monday to Friday, until 1 December. View on application to Librarian.

Grants and Awards

The 1967 triennial Gower's Essay Prize on Epilepsy has been awarded to Dr. D. C. Taylor, Guy's Maudsley neurosurgical unit.

The British Empire Cancer Campaign for Research has announced grants to individual research workers amounting to £196,000. Nearly £25,000, the largest grant, will support a study of the basic mechanisms of cell differentiation that is being carried out by Dr. J. Paul, director of the cancer research department at the Royal Beatson Memorial Hospital, Glasgow. Dr. I. R. McWhinney receives a grant of £1,529 for an investigation into the presenting symptoms of cancer in general practice.

The Wellcome Trust is making a grant of £17,000 over two years in support of a study of sickle cell anaemia in Jamaica. The study will be conducted by the departments of medicine and haematology at the University of the West Indies.

The Royal Society announces that the Beringer Research Fellowship has been awarded to Dr. H. Festenstein, of the McIndoe Memorial Research Unit, to enable him to carry out research on histocompatibility—investigations of antigenic strength by cell cultural techniques in mice and the application of these techniques and that of serological typing to the selection of donors for renal transplantation in man—in the department of medicine and bacteriology, London Hospital Medical College.

Recent Publications

Hospital Services of Europe: report of the third European conference held in October 1966 by the International Hospital Federation in collaboration with the King's Fund. Copies can be obtained from the International Hospital Federation, 24 Nutford Place, London W.1, 10s. post free.

Commonwealth Collections of Microorganisms: *Directory of Collections and List of Species Maintained in Canada, 1967,* H.M.S.O., 9s. net.

Report on Safety, Health, Welfare, and Wages in Agriculture, 1 October 1965 to 30 September 1966, H.M.S.O., 2s. 3d. net.

A new British Council pamphlet *The Married Student: A Guide to Life in Britain* (price 6d.) is intended to help the overseas student to decide whether his wife (and children) should accompany him on his course of study. It supplements the handbook, *How to Live in Britain,* published for the British Council by Longmans, Green (price 1s.).

A Ministry of Housing and Local Government circular calls on local authorities to reduce air pollution caused by grit and dust discharged from boiler and furnace chimneys. It directs their attention to the report of a working party on grit and dust emissions (H.M.S.O., 3s.) and to a booklet, *Grit and Dust,* based on the report (H.M.S.O., 3s.).

Coming Events

British Society of Audiology.—Inaugural meeting, 8 September, 5 p.m., Royal Society of Medicine, 1 Wimpole Street, London W.1.

British Association of Manipulative Medicine.—Symposium by Mr. W. E. TUCKER on "Treatment of Athletic Injuries," Sunday, 24 September, 11 a.m., in London. Details from honorary secretary, 3 Arundel Terrace, Brighton 7, Sussex.

Royal College of General Practitioners (West of Scotland Faculty).—Residential course for new entrants to general practice, 25–29 September. Details from honorary secretary, West of Scotland Faculty, Royal College of General Practitioners, 9 Lynedoch Crescent, Glasgow C.3.

Association of Medical Record Officers.—Conference, "Computers and the Hospital Service," 5–6 October, Dental Hospital, Birmingham 4.

University of Salford Postgraduate Medical Institute.—Symposium, "Techniques of Behaviour Therapy," 21 October.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Wednesday, 30 August

STOKE MANDEVILLE HOSPITAL.—(1) 12.15 p.m., Dr. W. Stokes: clinical cases. (2) 6 p.m., Dr. H. Frankel: case demonstration.

Friday, 1 September

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. R. Bignall: clinical demonstration.

Appointments

BIRMINGHAM REGIONAL HOSPITAL BOARD.—H. V. Morgan, M.B., F.R.C.P. (whole-time consultant physician with special experience in tropical medicine and communicable diseases to the East Birmingham group); S. P. B. Way, M.D., M.R.C.P. (whole-time or maximum part-time consultant pathologist to the Dudley and Stourbridge group); J. S. Mather, M.B., F.F.A. R.C.S. (part-time consultant anaesthetist to the United Birmingham Hospitals and the Birmingham (Selly Oak) group); G. B. Simon, M.B., D.P.M. (whole-time or maximum part-time consultant psychiatrist and medical director to the Mid-Worcestershire group).

HOME OFFICE.—I. A. Angus, M.B. (principal medical officer—regional medical officer, Prison Medical Service, N.W. region).

NATIONAL HEART HOSPITAL.—A. Gilston, M.B., F.F.A. R.C.S. (consultant anaesthetist); J. K. Ross, M.B., M.S., F.R.C.S. (consultant surgeon); M. J. L. Patterson, M.B., M.R.C.P. (consultant pathologist).

NATIONAL HOSPITALS FOR NERVOUS DISEASES, Queen Square, London W.C.—(Mrs.) Doreen A. Jewkes, M.B., F.F.A. R.C.S., D.A. (consultant anaesthetist to the National Hospital, Queen Square and Maida Vale Hospital).

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—J. L. Reed, M.B., M.R.C.P., D.P.M. (consultant psychiatrist to Hackney and Queen Elizabeth group of hospitals and senior lecturer at St. Bartholomew's Hospital Medical College); J. A. Rumble, M.B., F.R.C.S., D.O. (consultant ophthalmic surgeon to Southend-on-Sea group of hospitals); Nina Shotts, M.R.C.S., F.D.S. R.C.S. (consultant dental surgeon to Tottenham and Enfield group of hospitals); A. N. Cammock, B.M., D.L.O. (consultant E.N.T. surgeon to Thames and Forest groups of hospitals); V. M. Tarkunde, M.B., F.F.R., D.M.R.E. (consultant radiologist to Romford group of hospitals).

Universities and Colleges

LONDON

The following have been reappointed or renominated as representatives of the University on the governing bodies indicated in parentheses: Dr. C. F. Harris and Professor J. G. Scadding (British Postgraduate Medical Federation); Sir E. Rowan Boland and Dr. J. Forest Smith (Guy's Hospital Medical School); Professor F. Goldby and Dr. C. E. Newman (King's College Hospital Medical School); Professor M. de B. Daly and Dr. M. I. A. Hunter (Royal Dental Hospital of London School of Dental Surgery); Dr. D. H. Brinton (St. George's Hospital Medical School); Professor R. S. F. Schilling (St. Thomas's Hospital Medical School); Dr. J. H. Humphrey, F.R.S. (University College Hospital Medical School).

The following have been recognized as teachers of the university in the subjects indicated in parentheses: *St. Mary's Hospital Medical School,* Dr. R. G. Bannister (medicine (neurology)). *St. Thomas's Hospital Medical School,* Dr. T. H. Foley, Dr. C. Rosendorff (medicine). *London Hospital Medical College,* Mr. A. W. Morrison (otolaryngology). *Guy's Hospital Medical School,* Mr. L. F. W. Salmon (otorhinolaryngology), Dr. H. M. Saxton (radiology), Dr. R. J. Vale (anaesthetics).

M.D.—G. G. Muir, N. McIntyre, B. B. Obeng.

M.PHIL.—*In the Faculty of Medicine:* Beatrice E. Bolger, Linette D. Iliff.

PH.D.—*In the Faculty of Medicine:* L. Black, R. P. Enever, Sally D. Everett, S. S. H. Nasser, H. C. B. Reed, Shirley H. Wray, M. M. Abou-El-Makarem, Valerie A. Cowie, T. K. Dasgupta, J. S. Greenspan, K. Nuki.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At the meeting of council held on 28 July, with the president, Sir John Peel, in the chair, the following were admitted to Fellowship:

F. G. Grant (Northern Ireland), T. G. Robinson (United Kingdom).

The following were admitted to Membership:

Needs of Mentally Subnormal: Only about half of such patients seen in Birmingham required hospital care, and referring the remainder to the local authority would result in a better all-round service, according to Professor T. McKeown and Dr. I. Leck (p. 573). Leader on this page.

Heart Block: "Demand" pacemaker avoids competition between artificial pacemaking and returning normal sinus rhythm, and Dr. E. Sowton has found such a device to be clinically reliable (p. 576).

Phenylketonuria: Drs. J. B. P. Stephenson and M. S. McBean found that temporary phenylalanine hydroxylase deficiency is indistinguishable from phenylketonuria in early infancy, and therefore diagnosis should be re-examined lest treatment induce phenylalanine deficiency in a normal child (p. 579). They also report that mass screening by napkin-Phenistix test is not efficient for early detection (p. 582).

Treating Varicose Veins: Reliable method of detecting incompetent perforating veins by operative venography described by Mr. J. Townsend and colleagues (p. 583).

Myocardial Infarction in Pregnancy: Dr. E. Fletcher and colleagues describe five cases in elderly multigravidae (p. 586).

Hazards of Piped Air Supplies: Contamination by oil mist from compressors in the system detected by Drs. J. A. Bushman and P. A. Clark (p. 588).

Symptoms of Cerebral Metastases: These may be simulated by hypercalcaemia, and Dr. N. J. Strickland and colleagues report a case of bronchial carcinoma without bony or cerebral metastases presenting in this way (p. 590).

Oxygen Therapy: Dr. I. D. Green considers method used should depend on the patient's comfort, degree or risk of hypercapnia, and quality of supervision (p. 593).

Phagocytosis in Renal Failure: Dr. T. D. Brogan reports studies of phagocytosis by polymorphs in uraemic patients (p. 596).

Injection Complication: Subcutaneous atrophy after local corticosteroid injection suggests that deep injections of more dilute suspensions are preferable (p. 600).

Chlorate Poisoning: Successfully treated by peritoneal dialysis (p. 601).

Drug Addiction: Dr. T. H. Bewley writes on the drugs taken, the sources of supply, and the treatment of the addict (p. 603). Leader on S.T.P. (p. 570).

Diagnostic Virology: Inception of a comprehensive diagnostic service described by Dr. J. E. Banatvala and colleagues (p. 609).

Benefits of Automation: Use of computer to supply missing mortality data suggested by Mr. M. R. Hubbard and Dr. E. D. Acheson (p. 612).

Medical Registration: *Supplement*, p. 125.

Place of the Mentally Retarded

There is a continuum in the distribution of intelligence between highly gifted people at one end of the scale and idiots at the other. Thus no natural cleavage separates people who may be regarded as "mentally subnormal" from those of normal intelligence. Any division is arbitrary and a matter of convenience. An intelligence quotient of 70 on a properly standardized and administered test has achieved international recognition as a convenient boundary. This may result in 1.5% of a population such as ours being classed as "subnormal" by this criterion alone, or about 750,000 of a 50,000,000 population. Most of these people find their own niche in society and are an integral part of it. Clearly no special search should be made to "ascertain" this large number or to make special provision for them. There is not enough provision for those who are already known to hospitals and local authorities.

Social changes over the past half-century, together with a better understanding of the balance and distribution of human intellectual endowment, have led to a complete change of direction in the services for the mentally retarded. In 1909 the Eugenics Society was founded, and A. F. Tredgold,[1] writing in the first number of *Eugenics Review,* revived Morel's doctrine[2] of national degeneracy, which he described as "no myth but a very serious reality." Tredgold held that legislation concerning mental defectives was overdue, claiming that "the chief evil that we have to prevent is undoubtedly that of propagation." In 1913 the Mental Deficiency Act was passed, which restricted to the Board of Control the right of discharge of mentally deficient patients in institutions. However, N. Goodman and J. Tizard[3] found in 1962 that so far as imbeciles and idiots are concerned there is no evidence that their prevalence is increasing in Britain, possibly the reverse. Neither have surveys such as that carried out by the Scottish Council for Research in Education[4] supported the suggestion of a decline in national intelligence.

N. O'Connor and J. Tizard[5] showed ten years ago that with relatively little effort large numbers of institutionalized mental defectives could be placed in open employment in the general community. Official opinion now fully supports the view that so far as possible those of limited intelligence should be retained in the general community and placed in hospital or residential units only as a last resort. The report of the Royal Commission on the Law Relating to Mental Illness and Mental Deficiency[6] points out that the majority of the feebleminded are in the general community and that many are earning their living at simple occupations, and also that "There is increasing medical emphasis on forms of treatment and training and social services which can be given without bringing patients into hospital. . . ."

Though for over a decade the numbers of the mentally ill in hospital have fallen steadily, the numbers of the mentally retarded have tended to increase. They rose from 24,000 in 1929 to 56,000 in 1952, while in 1965 the number of subnormal and severely subnormal patients in

© *British Medical Journal,* 1967. All reproduction rights reserved.

psychiatric beds was 64,000.[7] The British Psychological Society appointed a working party, which looked at one aspect of this problem.[8] They showed that there seemed to have been little change in the proportion of more intelligent patients in hospital since the earlier work by O'Connor and Tizard.[5] For patients seen by psychologists in hospital (admittedly a selected sample) the average Wechsler I.Q. on admission was over 70, and, still more surprisingly, the average for the severely subnormal was 60. Their findings strongly suggest that if adequate resources in the way of psychiatric social workers, psychiatrists, employment officers, and others were deployed on rehabilitating the brighter patients then many more of them could be kept out or got out of hospital and into employment. Major obstacles at present are the difficulty of finding suitable lodgings and the dearth of open hostels.

This week in the *B.M.J.* Professor Thomas McKeown and Dr. Ian Leck review at page 573 some of the inadequacies of the hospital service in the light of the Ministry of Health Memorandum (65) 104 *Improving the Effectiveness of the Hospital Service for the Mentally Subnormal.* They have carried out a very useful survey of the mentally subnormal population in hospital at Birmingham, analysing it according to the needs of different groups of patients. The cost of the service is low—£9 per week compared with £15 for "chronic conditions," and £38 for acute children's illness, with beds for mental subnormality at the bottom of the price list. And the authors point out that the result is an inadequate rather than an economical service. In fact the investigation by the British Psychological Society points to a considerable reduction of numbers of inpatients which could be made almost immediately if the psychiatric team functioned as a vigorous rehabilitation unit and was suitably reinforced for this purpose.

McKeown and Leck suggest that responsibility for training should be transferred from the local health authority to the education authority and that a group of resident patients should be transferred to the local health authority. These ideas are logical but will be of no avail unless they are part of a larger and more radical overhaul of the system. If training centres are to go to the education authority they must be staffed by trained teachers specially qualified in the education of handicapped children, or at the very least the Scott Report[9] must be implemented in full and urgently. If patients now resident in hospital are to go to the local authority many new small residential units with adequate staff are required. This should be done not simply by passing the onus to the local health authority but by joint detailed planning and joint operation with the full support of the psychiatric team, including psychiatrist, psychologist, and social worker, so as to get the best use of the limited talent available, as described in the Brooklands experiment.[10]

Finally, both the Ministry circular and McKeown and Leck mention research, the lack of which has contributed powerfully to neglect of the problem of mental handicap. It would seem that thousands of pounds are readily spent on housing a patient for perhaps 40 or 50 years, while a few pounds per head of the institutional population cannot be found to advance studies on rehabilitation and causation.

Training for Obstetrics and Gynaecology

Under the chairmanship of Professor C. H. G. Macafee a select committee of eminent gynaecologists has reported to the Council of the Royal College of Obstetricians and Gynaecologists on training for the practice of that specialty.[1] They have considered the teaching of obstetrics and gynaecology to undergraduates, the training and further education of general practitioner obstetricians, the training of specialists, research in obstetrics and gynaecology, the recruitment of specialists, and the staffing and organization both of teaching departments and of hospital departments of obstetrics and gynaecology. The select committee obtained its information from questionaries sent out to academic and part-time consultants, and the questions covered undergraduate education, preregistration students, the qualifications of specialist obstetricians and gynaecologists, staffing, research, and other matters. A questionary was also sent to final-year undergraduate medical students asking them to give their views on obstetrics and gynaecology and its teaching and why they would or would not choose this specialty as a career. With the information thus gained Professor Macafee visited several centres to gain first-hand knowledge of the problems of education, research, and recruitment.

The Committee have digested the information obtained for them and have produced an interesting picture of the state of obstetrics and gynaecology in Britain today. It might well be said that the facts and opinions on which the report is based are far from exhaustive, since only 55% of the undergraduate questionaries (nearly 1,000 replies) were returned, and from consultants there were 83 replies. But despite the relatively poor response rate the committee's views alone are worth having, for they confirm an uneasy feeling that all is not well with obstetrics and gynaecology. A similar rather gloomy view came from the United States in 1961.[2]

The report seems to be seeking a status for obstetrics and gynaecology within the field of medicine as a whole. The subject appears to be undervalued, and the document is a statement of faith in its future. It has been realized that a mechanistic view of reproduction and its disorders no longer meets the needs of today either in education or in practice, and something must be done about it if top-quality teachers and practitioners are to be attracted to the specialty. The report often refers to "our specialty," giving perhaps a hint of parochialism, exclusiveness, and separateness which may occasionally be seen to beset obstetricians and gynaecologists. Everyone will agree with the committee, however, that obstetrics and gynaecology is a subject deserving the attention of first-class minds, and it has useful recommendations that point the way to escape from narrow intellectual confines, it being necessary to "eradicate the old picture of obstetrics being a manipulative art and gynaecology a narrow branch of surgery."

---

[1] Royal College of Obstetricians and Gynaecologists, *The Training of Obstetricians and Gynaecologists in Britain, and Matters Related Thereto*, The Report of a Select Committee to the Council of the College, 1967. London.

[2] *The Recruitment of Talent for a Medical Specialty*, ed. Howard C. Taylor, jun., 1961. Saint Louis.

Students come to obstetrics and gynaecology full of enthusiasm, but this later fades, probably because of lack of intellectual stimulus and because of the demands of practice. There is little doubt that the aspirant to consultant status has a long, hard clinical grind involving much time resident in hospital and in relatively understaffed departments, necessitating long periods of separation from his family. Hospital authorities have been slow to recognize the importance of married quarters for many of their staff, but there would seem to be a special claim for resident obstetricians to be so catered for.

Most disturbing for the Royal College must be the conclusion that "obstetrics and gynaecology does not attract its full share of those who show outstanding ability as undergraduates." The reasons suggested for this are the heavy burden of clinical work with little time for study during training, long residence in hospital, slower promotion to consultant status than in other specialties, the limited scope of the subject, and poor research facilities.

If the report presents a true image of obstetrics and gynaecology, the senior members of the specialty must bear their full measure of responsibility for it. If they had had enthusiasm, dreamed dreams, and seen visions, the medical world would not have such a drab view of what obstetrics and gynaecology is. Undoubtedly the blinkers are being removed—and this report is a sign that they are. It is to be fervently hoped that its recommendations will be acted upon.

Antibodies in Schizophrenics

In recent years several groups of workers have found abnormalities in the proteins in the blood of schizophrenic patients,[1-5] while others have reported that the administration of serum from schizophrenics produces changes in behaviour of rats[6 7] and monkeys.[8] Attempts to duplicate these findings have sometimes been unsuccessful,[4 9 10] and it is still not clear how consistent these abnormalities are and how specific they are for schizophrenia.[11] Interest in the blood proteins of schizophrenics is largely the result of the work of R. G. Heath and his colleagues[12] in New Orleans. In 1958 they reported that "taraxein," a protein isolated from the serum of schizophrenics, would cause electroencephalographic and behavioural changes in monkeys and that it would reproduce many of the symptoms of schizophrenia in human volunteers.

If an abnormal protein is present in the blood of schizophrenics it may be an antibody. Searches for an antigenic abnormality in serum from schizophrenics have yielded both positive[13] and negative[14] results. Russian workers,[15] using a complement-fixation technique, found antibrain antibodies in a considerable proportion of schizophrenics and other psychotic patients, but their findings have not been confirmed by other workers using a more specific precipitin reaction.[16 17] P. R. J. Burch[18] has postulated an autoimmune origin of schizophrenia on theoretical grounds from a study of age- and sex-specific rates of first admission to hospital.

Recently Heath and his colleagues, continuing their work on taraxein, have reported results of a series of immunological investigations.[19-21] Brains were obtained at necropsy from both schizophrenic patients and controls. When brain sections were incubated with fluorescein-tagged antihuman gammaglobulin (F.T.A.-Hgg), fluorescence was observed in the nuclei of nerve cells in the septal region and in the basal caudate nucleus of schizophrenics' brains but not of control brains. When the sections were first incubated with serum from schizophrenics, F.T.A.-Hgg produced slight fluorescence in sections from the same areas of control brains, and intense fluorescence in sections of schizophrenic brains. Control sera had no such effect. When sections of schizophrenics' brain were pretreated with untagged antihuman gammaglobulin, the fluorescence produced by F.T.A.-Hgg was greatly reduced.

These results certainly suggested that antibody is attached to nerve cells in certain areas of the brains of schizophrenics and that the antibody is present in serum from schizophrenics.[19] Further experiments suggest that the antibody can combine with the nuclei of nerve cells in monkeys' brains.[20] Finally, antisera against specific areas (including the septal area) of both human and monkey brain were produced by the injection of homogenates into sheep. Fractions of the antisera were administered to monkeys and caused electroencephalographic changes (especially from the septal area) and behavioural changes which closely resembled those produced by taraxein.[21]

At first sight these results offer good evidence of an autoimmune mechanism in schizophrenia. However, few workers would accept the E.E.G. and behavioural changes in monkeys as equivalents of schizophrenia in man. The discovery of antibody in schizophrenics' brain and serum is of great interest, and this part of the experiment at least should be repeated in other laboratories. But a word of caution is needed before too many conclusions are drawn. The history of research into the causes of schizophrenia consists of a dishearteningly long series of promising leads which ultimately led nowhere. The taraxein theory, on which the whole of the present series of experiments was based, may go the same way. Indeed it does not command general assent. Furthermore, the fluorescent antibody technique can give rise to false positive results unless the greatest care is taken; unfortunately the authors do not give details of how they measured the fluorescence. Nor do they deal with the objection that there is no histological evidence of immunological damage in the brain of schizophrenics.[17] Finally, autoimmunity is a fashionable concept for explaining the origin of several other chronic, relapsing diseases as well as schizophrenia. It is salutary to recall that focal sepsis was once just as fashionable[22] and

that it was offered, with much evidence, as a cause of schizophrenia.[23] During attempts to remove some of the less accessible foci, many patients died. At least the theory of autoimmunity is unlikely to lead to such therapeutic disasters.

Progress with Air Pollution

Since the winter of 1962 the National Survey on Air Pollution has been collecting data throughout the year on the concentration of smoke and sulphur dioxide in a representative sample of British towns. The data are processed by computer and are available to all interested workers through the Warren Spring Laboratory, Stevenage. In its 32nd Report,[1] covering a period of eight years since the establishment of the first smoke control areas, the Warren Spring Laboratory discusses the trends in the pattern of pollution as a consequence of the Clean Air Act of 1956[2] and of the changing fuel requirements of modern technology.

There has been a decrease in the consumption of coal with an increase in that of fuel oil, most of which has a high sulphur content. As a result the emission of smoke into the atmosphere has fallen while that of sulphur dioxide has risen. The decrease in smoke concentration in the ambient atmosphere was to be expected, but there has also been a welcome decrease in the sulphur dioxide concentration over the country as a whole, with a smaller decrease in London. This has been attributed to the care which is now being given to the location of new industrial sites and such factors as the height and design of industrial chimneys.[3] The level of pollution depends on the amount of material emitted and on the weather conditions determining how much pollution is blown away, so that the weather is a major factor in setting the pattern of pollution from year to year. Since the Warren Spring studies show considerable fluctuations from one year to the next any trend so far must be interpreted with caution.

While the Clean Air Act is helping to clear the air of smoke, the removal of sulphur dioxide from it presents a greater problem. The report points out the high cost of the process for removing sulphur dioxide at the Battersea and Bankside power stations and the lack of success in developing a more convenient system. At Battersea 20–30 tons of Thames water are used for every ton of coal burnt, and extension of the process is limited by the capacity of the river to take the effluent. The most practicable way at present of limiting pollution from sulphur dioxide is by sending it aloft by means of suitable chimneys and with a high speed of emission, so that the gas is diluted before coming down again.

Studies at Stevenage and Hornsea on the distribution and dispersion of pollution in streets carrying heavy motor traffic have shown that though pollution can be high it is also extremely local in character. The black smoke from diesel engines arouses public indignation, but petrol engines produce more carbon monoxide and higher concentrations of unburnt hydrocarbons, which are more likely to be injurious to health.[4] Devices for removing smoke from diesel exhausts are uneconomical. The solution lies in the correct maintenance and operation of the vehicle, and this should be controllable by adequate legislation. However, according to a report[6] issued by the National Society for Clean Air last week, if all manufacturers set their engines to the level permitted by a forthcoming British Standard, smoke on the road would increase. In the U.S.A. stringent regulations will apply to all 1968 petrol engines, limiting the discharge of carbon monoxide and hydrocarbons. Britain is free of the irritant photochemical smog produced by the action of strong sunlight on unburnt hydrocarbons which is so characteristic of Los Angeles,[7] but the dangerous effects of a build-up of carbon monoxide are equally applicable here, and this problem has not yet been given sufficient attention.

That air pollution worsens the plight of a patient with chronic lung disease is undoubted, and it is likely to contribute to the production of chronic bronchitis. But there is no proof yet that either smoke or sulphur dioxide in the concentrations encountered in polluted air are the substances causing the harm, though they may be. However, since the concentrations of other harmful substances are likely to vary in the same way as those of smoke and sulphur dioxide, these two are likely to remain at least useful indices of air pollution.

S.T.P.

By the standards of " pop " culture S.T.P. is an elderly drug ; it has been publicly discussed for nearly two months. On 16 June *International Times*, the fortnightly newspaper of the hippie movement, predicted its arrival in Great Britain,[1] by mid-July a tablet had been passed to the Home Office for analysis,[2] and by the end of July *International Times* had reported that the drug was in wider use in Britain[3] and warned that it could be dangerous.

The American Food and Drug Administration has identified S.T.P. as methyl dimethoxy methyl amphetamine,[4] a substance chemically related to both amphetamine and mescaline, but a good deal of doubt remains. *Time*,[5] which gives the credit for the distribution if not the synthesis of this latest hallucinogen to a San Francisco chemist, reports that the drug may be 5-methoxy-NN-dimethyltryptamine. This substance is related to the known hallucinogens bufotenine, dimethyltryptamine, and psilocybin, and also to a principle in reed canary grass which causes staggers in sheep.[6] It has also been suggested that S.T.P. is related to a group of hallucinogens, the piperidyl glycolates, studied in the 1950s by L. G. Abood and his collaborators[7] or to a chemical warfare agent called BZ.[5] These suggestions are based on the cholinergic effects of S.T.P. Alternatively, S.T.P. may well be related to a group of benzilic acid derivatives, of which the tranquillizer benactyzine, the hallucinatory anti-Parkinsonian compound benzhexol, the arousing drug pipradol, and the enzyme potentiator S.K.F. 525 are other examples. S.K.F. 525 proved to be so powerful and so non-specific a substance that it was useless for therapy: the reported dangerous potentiation of S.T.P. by the usual antagonists of lysergic acid diethylamide (L.S.D.)[2,3] suggest that it may be just such another substance.

Not surprisingly, no controlled experiments have yet been done with S.T.P., but there seems little doubt that it is an active, dangerous, and powerful substance. A single dose (however much that may be) is said to give a 72-hour " trip,"[5] and the risk of suicide or psychotic breakdown seems likely to be correspondingly greater than with L.S.D.

Whatever its identity, the emergence of S.T.P. has raised several questions of interest. Whose is the responsibility to collect and sift information on drugs introduced in this way, to promote research, and to advise society on their control and appropriate uses ? Perhaps the L.S.D. and Cannabis Subcommittee of the Home Office's Standing Advisory Committee on Drug Dependence should extend its terms of reference to include drugs of this kind as they are developed. L.S.D. was not the first hallucinogen: S.T.P. is certainly not the last. New compounds may be developed with totally new actions for which the appropriate scientific descriptive language does not yet exist—a fact that may itself contribute to anxiety about such drugs. The definitive chemical identification of S.T.P. has probably been delayed as a result of deliberate obfuscation by those responsible for its synthesis and distribution—several different substances were apparently sold or given to the Federal Drugs Administration as S.T.P. by its informants.[4]

The iconoclasm of hippiedom and the ill-considered advocacy of people who should know better, including, unfortunately, a few members of the medical profession, are acting together to create an atmosphere in which firm action to control the spread of drug-taking is unpopular. Nevertheless, such action is needed. The statutory measures for the control of drugs need to be made more flexible, so that as soon as compounds such as S.T.P. enter circulation their unauthorized possession and distribution can be made an offence. Society has a responsibility to protect its members from drugs that can make them frankly insane or indeed kill them, as it has to stop the spread of communicable diseases.

Healing Processes in Wounds

Reactions to injury tend to be studied intensively in time of war and to be neglected in the subsequent peace. But fortunately for medicine the healing of wounds presents enough basic problems of deep interest to biologists to ensure that it remains a field of active research.[1] Though clinicians demand practical information about factors influencing healing, facts can come only from careful experimental work, and such experiments have already exposed some widely held fallacies.

The healing of a wound starts as an inflammatory reaction with infiltration by polymorphs and mononuclear phagocytes, and removal of debris by these cells. The reaction seems to be of importance to the subsequent healing. The ingrowth of new blood vessels, lymphatics, and nerves by budding from existing structures is relatively well established[2] and has fairly recently been confirmed by electron-microscopy.[3] A practical point is that new blood vessels are abnormally permeable to particulate matter,[4] including bacteria, and this may possibly facilitate infection of the wound from the blood stream.

The commonly held view of the origin of fibroblasts is that they migrate from the borders of the wound after division of existing fibroblasts. Alternatively it has been suggested that fibroblasts may be derived from haematogenous mononuclear cells.[5] However, all spindle-shaped cells in granulation tissue are not fibroblasts. The fibroblast can be identified with certainty only by electron-microscopy. It is then seen to have a large nucleus and nucleolus, extensive rough-surfaced endoplasmic reticulum, dense cytoplasmic bodies, peripheral cytoplasmic vesicles, dispersed Golgi network, numerous large mitochondria, and aggregates of fine filaments at the periphery of the cell.[6] The possibility that blood cells turn into fibroblasts may perhaps be proved only by use of blood cells labelled with a stable marker in conjunction with electron-microscopy.

Experimental studies show that collagen is synthesized by hydroxylation of proline and then biosynthesis of the protein in the endoplasmic reticulum of the fibroblasts. From here the protein passes into the extracellular space, where it acquires the characteristic banding (700 Å) of collagen. The mitochondria are not significantly involved in this process but the Golgi complex and peripheral vesicles are, especially if the collagen is destined to enter into a complex with polysaccharide. The clinical relevance of these observations is apparent from study of scorbutic animals, vitamin-C deficiency being one cause of defective healing of wounds. In scurvy wounds are normal except for the absence of collagen fibrils. Electron-microscopy shows the fibroblasts have an abnormal endoplasmic reticulum, with plenty of ribosomes but lack of regular orientation. Filamentous extracellular material (presumably fibrillar protein) is present, but this lacks the regular banding of collagen. It is not yet clear whether failure of wound healing in vitamin-C deficiency is due to changes in the properties or the structure of fibroblastic ribosomes and endoplastic reticulum or whether these are secondary to a failure to hydroxylate proline.[7]

In addition to the synthesis of collagen, contraction of the wound area is a vital part of healing. It is now realized that this phenomenon is not due to contraction of collagen fibres or to loss of extracellular or intracellular water. Nor is it due to ingrowth of epithelium from the wound margins. The contraction is in fact a complex and poorly understood process, yet it is of great importance in living tissues. It seems to be due to tensions within the granulation tissue filling the wound, orientated towards lines of stress, and associated with removal of cells and extracellular material, including collagen.[8-10] Likewise the cessation of wound contraction is also of clinical importance. M. Abercrombie[10] believes that it may occur when the advancing edges of the

skin approach within a certain distance of each other. Most collagen is laid down after contraction ceases, possibly because it is only then that the contents of the wound are under tension.

Another feature of the healing of wounds is epithelization. A covering of epithelium often grows in advance of the contraction process and without hindering it. The classical view that mitotic activity in epithelium is confined to the edges of a wound is true only of skin and some other sites. Nevertheless, it is best to consider epithelial proliferation and epithelial migration as separate phenomena of healing.[11] Current views tend to regard the destruction of the normal cell architecture of a tissue (" negative feedback ") rather than local hormones as leading to cell proliferation in healing.[12] It is now known also that denervation has no effect on healing provided the wound is protected from trauma.[13]

Despite advances in knowledge obtained by research workers recently surgeons are in practice sometimes baffled by the unpredictability of the healing process. Of special note, therefore, is a report by a surgical team of dramatic acceleration of healing of open wounds in patients given zinc sulphate 2 mg. three times daily by mouth.[14] The results suggest that the process affected was wound contraction, and they indicate a state of zinc deficiency in a group of healthy, well-fed, young American males. It is possible that trauma, burns, or other stress may greatly increase the short-term need for zinc and that this deficiency cannot be made good by a normal diet. The action of zinc would presumably lie in providing a prosthetic group for enzymes required for wound healing. Certainly activation of enzymes occurs in wounds,[15] and some of the enzymes are of the type to require metallic prosthetic groups. The results obtained with zinc sulphate offer a straw at which surgeons may be prepared to grasp, especially as no ill effects were reported.

Diet and Alcohol in Gout

A low-purine diet has been used in the treatment of gout for many years, because reduction in purine metabolism will lower the synthesis of urate. A high-purine diet may cause the level of uric acid in the serum to rise. For example, F. G. W. Marson,[1] in a study of eight patients (seven of whom were hyperuricaemic), showed that a change from a low- to a high-purine diet raised the serum uric acid by an average of 1.3 mg./100 ml. In a patient who is already mildly hyperuricaemic such a rise might be sufficient to produce clinical gout.

It is remarkable, however, that the effect of fasting on the level of uric acid in the serum is equally striking. That it may produce hyperuricaemia, with a reduction in the urinary excretion of urate, has been known at least since 1909.[2] The hyperuricaemia appears to be due to increased levels in the serum of β-hydroxy-butyric acid and acetoacetic acid, with a resulting ketosis. This has the effect of interfering with the renal excretion of uric acid and lowers the ratio of urate clearance to creatinine clearance.[3-5] Fasting in one recent study[6] caused an average rise, above the base-line achieved on a low-purine diet, in the serum level of uric acid of 1.1 mg./100 ml. after 24 hours in five gouty patients and an average rise of 2.0 mg./100 ml. after 48 hours in a further eight patients. In practice potent uricosuric drugs and xanthine-oxidase inhibitors have a profound effect in lowering the serum level of uric acid in gouty patients, and in ordinary circumstances a low-purine diet gives only a marginal benefit, if any at all.

The association between alcohol and gout is traditional. In fact patients will sometimes deny a family history of gout for fear that the doctor will interpret this as evidence of alcoholism. Nevertheless, there is some truth in the belief that taking alcohol may provoke an attack. The serum uric acid is indeed higher when a patient is acutely intoxicated than when sober.[7] This is apparently associated with lactate, which inhibits renal excretion of urate,[8, 9] and is increased in the blood in alcoholic intoxication. The administration of lactate to patients will cause hyperuricaemia.[7, 10] F. P. Alepa and his colleagues[11] and S. Jakovcic and L. B. Sorensen[12] have both recently demonstrated a raised serum lactate level together with hypoglycaemia and ketonaemia in association with hyperuricaemia in patients with glycogen storage disease. In these cases the hyperuricaemia is due to a reduced renal clearance of urate and also to increased biosynthesis of purine.

It is possible that many true alcoholics combine a high intake of alcohol with lack of food, so that the combined effect of these two factors, each capable of producing hyperuricaemia, may be more profound. M. J. Maclachlan and G. P. Rodnan[6] have confirmed that small amounts of alcohol cause only a slight rise in serum uric acid, but when the alcohol was taken during a short period of fasting the rise in the serum uric acid was greater than that which followed fasting alone.

Thus a high-purine diet, fasting, and alcohol intake are associated with acute attacks of gout. Furthermore, it is known that sudden changes in the serum level of uric acid may provoke an acute attack of arthritis whether the serum uric acid is rising or falling. It is a common experience that acute gout may be precipitated by treatment either with uricosuric drugs, such as probenecid,[13] or with allopurinol,[14] both of which lower the level of serum uric acid in different ways. Maclachlan and Rodnan's study[6] again showed that rapid fluctuations in serum uric acid, usually exceeding 1 mg./100 ml., were associated with acute attacks of gout, 13 out of 19 attacks occurring in relation to a rapidly falling serum level of uric acid and six with a rising level.

Since we can now exercise metabolic control of gout readily by correction of hyperuricaemia with potent drugs, the use of a low-purine diet has become of little advantage to the patient. Moreover, since the acute attacks of gout may be precipitated by rapid fluctuations in serum levels of uric acid the patient should avoid alcoholic excesses, maintain an adequate food intake, and be on a constant regimen of drug therapy.

Papers and Originals

Institutional Care of the Mentally Subnormal*

THOMAS McKEOWN,† M.D., PH.D., D.PHIL., F.R.C.P.; IAN LECK,‡ M.B., PH.D.

Brit. med. J., 1967, 3, 573–576

The trend of progressive opinion concerning the hospital care of the mentally subnormal is well expressed in a Ministry of Health Memorandum [(65)104] on *Improving the Effectiveness of the Hospital Service for the Mentally Subnormal.* It states: "In the absence of complicating conditions, such as severe physical disability or disturbed behaviour, the severely subnormal patient who has been adequately investigated and treated ought not to be primarily the responsibility of the hospital services for long-term care. Ultimately, when facilities outside hospitals are fully developed, continued hospital care will be necessary only for patients who require special or continuous nursing and for those who, because of unstable behaviour, need the kind of supervision and control provided by a hospital." Our object in this paper is to estimate the proportion of patients now in hospital who, according to these criteria, require hospital care and to consider the future organization of institutional care of the mentally subnormal in the light of the findings.

In 1965 an investigation was made of the needs of all (1,652) Birmingham patients (874 male and 778 female) in 13 hospitals for the subnormal in the Birmingham area. Each patient's requirements were assessed by a hospital doctor and nurse in charge of the ward. A previous report (Leck, Gordon, and McKeown, 1967) showed that in most respects Birmingham patients were similar to the subnormal in all hospitals in England and Wales. The exceptions were the lower proportion of young patients in Birmingham hospitals (accommodation for them in the area is deficient) and the higher proportion classified as "severely subnormal."

Classification of Patients According to their Needs

The earlier paper gave details of patients' requirements for medical care, nursing care, training, and occupation, and the results were brought together in an attempt to present a picture of the essential needs of the whole hospital population. As a basis for the present discussion the observations are summarized in Table I. The types of care are here arranged in order of decreasing complexity—from "investigation or active hospital treatment" to "sheltered environment"—and each patient is uniquely classified according to the most complex type of care he required.

TABLE I.—*Classification of Patients According to Type of Care Required*

Care Required	No.	%
Investigation or active hospital treatment	7	0·4
Mental and basic nursing	366	22·2
Mental nursing	286	17·3
Basic nursing	212	12·8
Checking and counselling	302	18·3
Sheltered environment	479	29·0
Total	1,652	100

Medical Treatment

Only seven of the 1,652 patients were thought to need medical investigation or treatment of a kind which would have made it necessary for them to be in hospital. This is much lower than the estimate (10%) made by Pilkington (1966) and confirmed by him in a recent survey (personal communication) of the proportion of his patients who required "detailed specialist, day-to-day diagnosis, care, and treatment." There are probably two main reasons for the difference.

Firstly, there is considerable regional variation in the pattern of care of the mentally subnormal. Birmingham is a relatively compact area in which paediatric and child psychiatric centres do a considerable amount of investigation which might elsewhere be done in hospitals for the subnormal. The mental hospitals are reasonably convenient and deal with more high-grade subnormal psychopaths than in some other regions. The pattern of care is also affected by the shortage (already referred to) of hospital accommodation for children.

But the estimate of the proportion of patients needing hospital investigation and treatment is also influenced by the judgement of the medical staffs on the scope for active measures. At the present time there are considerable differences of opinion and practice concerning the application of special methods. In some hospitals biochemical and structural abnormalities are investigated and a few centres are equipped for chromosome examination. Special units have been established for autistic children, for deaf subnormal children, for adolescents, for psychopaths, for psychotic children. In the United States, in the field of mental retardation, research is given high priority, and a large number of research units have been established in hospitals. Collectively these developments comprise the growing edge of the field of mental subnormality, but they have not yet greatly influenced the work of the average hospital, where active investigation and treatment are still restricted to a very small proportion of patients.

A further 794 of the 1,652 patients were considered to require treatment (mainly tranquillizers, anticonvulsants, sedatives) which would not have made it necessary for them to be in hospital. The remaining 851 patients were said to need no medical treatment.

Nursing Care

In relation to the organization of hospital care of the subnormal the most important features of the classification in Table I are the subdivision of the various types of nursing and the distinction between nursing and other forms of personal

---

* This investigation was supported by a grant from the Nuffield Provincial Hospitals Trust.

† Professor of Social Medicine, University of Birmingham.

‡ Wates Foundation Senior Lecturer in Community Medicine, University College Hospital Medical School, London W.C.1.

care. About half the patients (871) were thought to need nursing: the seven who required investigation or hospital treatment (which would include skilled nursing) and 864 in need of mental nursing and/or basic nursing. Mental nursing is taken to comprise the care and supervision of potentially difficult patients. Basic nursing includes personal services, such as washing, dressing, feeding, lifting, attention to bladder and bowel of the incontinent, which require only a limited degree of nursing skill and experience.

Checking and Counselling

The other 781 patients, about half of the total population, needed only "checking and counselling" or a sheltered environment without personal service. The distinction between mental nursing and checking and counselling is important. The latter are interpreted as advice about activities such as dressing, washing, and time-keeping; the patients concerned have to be reminded about these things, but apart from such advice they need no other personal service. It seems essential to distinguish this kind of care, which can be provided by untrained staff, from skilled, basic, and mental nursing for which training is required.

Relation of Hospitals to Other Services

According to the recommendation quoted in the opening paragraph (that hospital care should be restricted to those "who require special or continuous nursing and . . . who, because of unstable behaviour, need the kind of supervision and control provided by a hospital") the evidence presented in Table I suggests that about half the patients now in hospital should not be there. This is the proportion of patients who need no medical or nursing care, and who require, in addition to training and occupation, only a sheltered environment with, in some cases, the simple personal attention described as checking and counselling. The central question concerning the future organization of institutional care of the subnormal is whether the two groups of patients—those who need medical and nursing care and those who do not—should be in the same institution and under the same administrative authority.

Before attempting to answer this question we should remind ourselves of the present difficulties of mental subnormality hospitals, which are perhaps the most formidable confronting any branch of the hospital service. The most serious problem is their inability to attract staff, particularly skilled staff. A recent estimate of nursing strength in the Birmingham Region showed that the number of trained nurses in posts was about two-thirds of the establishment and the number of student and pupil nurses was only one-third. These deficiencies had to be compensated so far as possible by an increase in the number of enrolled and other assistant nurses, which was much above the establishment.

The difficulties of medical staffing are well known. A recent survey of consultant psychiatric establishments in mental subnormality hospital groups of 1,000 or more beds in England and Scotland (Heaton-Ward, 1967) showed that the number of beds per full-time consultant equivalent ranged from 260 to 1,185. The national average (628) was far above the figure (300) recommended by the Mental Deficiency Section of the Royal Medico-Psychological Association in 1960. The high consultant bed ratios for established posts are due largely to the lack of applicants for consultant appointments: some hospital boards see little point in creating posts which there is little prospect of filling. Similar difficulties are encountered in attracting other professional workers such as psychologists and physiotherapists.

But the deficiencies of the hospitals are not only in respect of medical and nursing care. The Birmingham investigation included an assessment of the occupation required by each patient, and Table II shows the proportions engaged in the occupations recommended for them. Of the 1,242 patients regarded as suitable for some type of activity, only about half (630) were in the occupation recommended, and 101 had no occupation of any kind. These results indicate that in many hospitals for the subnormal opportunities for education, training, and employment are very deficient.

TABLE II.—*Proportion of Patients in Recommended Occupation*

Occupation	No. of Patients Recommended	Patients in Recommended Occupation	
		No.	%
Training { Elementary	112	70	62·5
Training { Scholastic	8	3	37·5
Domestic work on wards	80	52	65·0
Therapeutic occupation or vocational rehabilitation	755	323	42·8
Work in hospital service departments	159	100	62·9
Work outside hospital	128	82	64·1
Total	1,242	630	50·7

The figures quoted here give some idea, though an inadequate one, of the difficulties of mental subnormality hospitals. They are unlikely to be resolved by minor modifications in practice, and require nothing less than a radical reorientation of hospital work in relation to other medical and social services.

The key to this reorientation, we suggest, lies in separating patients who need medical and nursing care from those who do not. Under present conditions the requirements of neither group can be well met: the medical care of the first is prejudiced by inflation of their numbers with patients without medical needs; and the educational and welfare services for the second group are quite inadequate because they are provided in a hospital environment and by the wrong authority. These difficulties could be removed by restricting the hospital responsibility to what is essentially the medical task, and by assigning to educational and welfare authorities patients who need training, employment, and a home.

Fig. 1 shows diagrammatically the present organization of services for the subnormal; the figures apply to the Birmingham population at the beginning of 1965. At that time there were under the health authority 116 children and 20 adults waiting for admission to hospital, and under the education authority 29 children needing admission to E.S.N. residential schools. Places were required for a further 133 children in E.S.N. day schools.

Fig. 2 shows the arrangements which would result from the proposed redistribution of responsibilities. The patients in

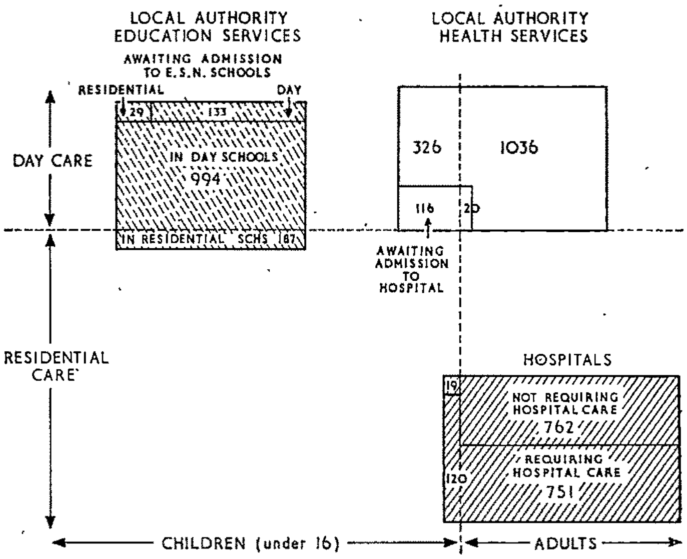

FIG. 1.—Diagram showing existing responsibilities for the subnormal. Birmingham, 1965.

hospital who need no medical or nursing care would be transferred for residential care to health or welfare departments (762 adults) or to the education department (19 children). In return the hospitals would receive the 116 children and 20 adults for whom admission was needed. E.S.N. residential and day schools are shown expanded to accommodate the children on their waiting-lists. Finally the remaining 326 children under the health authority in 1965 would be transferred to the education authority.

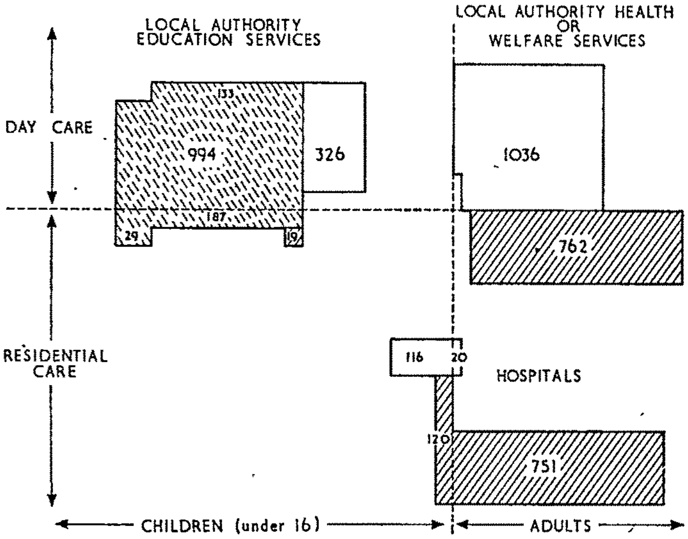

FIG. 2.—Diagram showing a proposed redistribution of responsibilities for the subnormal.

The last is possibly a controversial suggestion which is perhaps not essential to the present proposals. Such children have had advantages from being under the health department, and there is undoubtedly some risk that because of their relatively low potential for education they might be less well cared for under an education authority. Certainly the small number of children who can be kept at home in spite of substantial medical and nursing needs are best under the health department. But for most subnormal children living at home the main requirement is for education and training services, and we share the view expressed in a recent publication of the British Psychological Society (1966) that these services should be the responsibility of local education authorities. In Birmingham administration of the junior training centres has already been delegated by the health department to the education authority.

Hospital Care

We have seen that restriction of responsibility to patients "who require special or continuous nursing and . . . who, because of unstable behaviour, need the kind of supervision and control provided by a hospital" would reduce the hospital population of the subnormal to about half its present size. The way would then be open for reappraisal of the organization of hospital services, and particularly for consideration of the relation between subnormality hospitals and others.

As in the case of the mentally ill and chronic sick, it has been assumed hitherto that the subnormal should be segregated. This segregation results from historical circumstances and has had serious disadvantages which may be summarized as follows:

Heterogeneity of Patients.—Like other types of hospital patients, the mentally subnormal vary greatly in their medical, nursing, and social needs. Indeed they are the most heterogeneous of all hospital patients, since approximately half do not require medical and nursing services and should not be regarded as a medical responsibility.

Staffing Difficulties.—We have already referred to the formidable difficulty of providing staff, particularly professional staff. Again, as in the experience of mental and chronic hospitals, nurses and doctors cannot be attracted in sufficient numbers to institutions isolated from the main stream of professional interest. The problems which result from this isolation have been discussed fully and critically by Pilkington (1966). He refers not only to the effect of isolation on recruitment but also to its influence on the attitude of existing staff.

Excessive Hospital Size.—Though a good case can be made for large hospitals which receive all types of patients, they have serious disadvantages when their work is confined to a single class such as the mentally subnormal. Yet because of staffing and other difficulties in isolated institutions, concentration of patients is almost inevitable, and mental subnormality hospitals may have 1,000 or even 2,000 beds. The problem is aggravated by a number of administrative anomalies—for example, the linking of salary scales to bed numbers—which discourages discharge of patients and reduction of hospital size (Pilkington, 1966).

Lack of Research in Mental Subnormality.—In recent years there has been some increase in interest in the field of mental subnormality, but the pace of investigation is still very slow in relation to the size and variety of the problems. The remoteness of the hospitals from research centres, and particularly from teaching hospitals, undoubtedly contributes powerfully to this neglect. Indeed it seems unlikely that mental subnormality can receive the attention that is needed so long as the vast majority of hospital patients are in institutions rarely visited by research workers.

Costliness of an Adequate Service.—It could hardly be said that investment in the care of the mentally subnormal has been excessive, but the low cost has resulted from an inadequate rather than an economical service. If the level of care were raised to the standard now taken for granted in acute hospitals the cost in the existing segregated hospitals would undoubtedly be very considerable; for it would be necessary to reproduce laboratory and treatment services which already exist in other hospitals, but which cannot be used by the mentally subnormal so long as they are isolated.

These undesirable consequences of isolation point clearly to the need to unite mental subnormality and other types of hospitals. So long as the patients include large numbers who require no medical or nursing care, and so long as other hospitals—mental, chronic, and acute—are dispersed, this proposal is unrealistic. But if responsibility is restricted to patients needing medical and nursing care, and if major centres are designed for all other types of hospital work within a balanced hospital community (McKeown, 1958), it will be desirable to include provision for the mentally subnormal. In this way, and probably only in this way, will it be possible to raise the standard of their care to an acceptable level.

At least two objections will be raised to this proposal. It will be said that it would be unnecessarily expensive to care at a common hospital centre for patients whose medical and nursing needs are mainly basic nursing and psychiatric supervision. In reply we would say that while provision for the mentally subnormal, as for chronic and psychiatric patients, would be costly in the expensive wards of the traditional acute hospital, there is no reason why it should be so in appropriately designed facilities within a balanced hospital. Moreover, cost is not the only consideration, since history has shown that a satisfactory service cannot be provided in isolated institutions.

The other likely objection is that the number of beds required for the mentally subnormal is too large to be acceptable at a common site such as a district general hospital would offer. Some people are doubtful about the advisability of including all psychiatric patients, on the grounds that 175–350 beds (according to the optimism of the estimate) per 100,000 of population would create an imbalance between psychiatry and other services. The proposal to add a further 80 beds per 100,000 (the number suggested by our results) is certain to be resisted for the same reason.

These objections are rooted in a traditional view of hospital work in which the centre of interest is the patient with acute physical illness, and other types of patients—the majority—take a secondary place. The number of beds required for psychiatric and mentally subnormal patients is large because they comprise a considerable part of the total hospital population; and with the continued decline of acute illness their contribution, together with that of the aged sick, will be even larger. Medical research has not yet been very successful in unravelling the nature of these problems, and many patients still require prolonged care. But this is not a reason for accepting an inferior standard of care, and given well-designed services there are no financial or other grounds for not admitting all types of patients, including the mentally subnormal, at the same hospital centre in approximately the proportions in which they are found in the general population.

Summary

Investigation of the medical, nursing, and social needs of all Birmingham patients (1,652) in hospitals for the subnormal showed that only about half needed the kind of care—mainly basic nursing and psychiatric supervision—which made it necessary for them to be in hospital. The other half of the patients required training and occupation—both inadequately provided in hospital—in a sheltered environment with, in some cases, simple personal attention described as checking and counselling.

In accord with the recommendations of HM(65)104, it is suggested that hospital responsibility should be restricted to patients needing medical and nursing care and that the remainder should be transferred to local health, welfare, and education authorities. The reduction in the number of mentally subnormal patients in hospital would make it possible to care for them with all other hospital patients at a common centre. Only in this way will it be possible to focus research interest on the problems of the subnormal and to raise the standard of their care to an acceptable level.

For collaboration in the assessment of patients' needs we are indebted to the medical superintendents (Drs. R. A. Browne, A. P. Buchan, T. Crowley, A. S. Patterson, and R. J. Stanley) and staffs of the mental subnormality hospitals in the Birmingham Region. Dr. Stanley also provided valuable advice about the organization of the inquiry and the interpretation of its results. The data were collected and analysed with the help of Dr. W. L. Gordon, Miss Ida Giles, and Mrs. Betty Mann. National statistics relating to patients in mental subnormality hospitals were made available by Miss E. M. Brooke, of the Ministry of Health. Finally we should like to express our indebtedness to Dr. T. L. Pilkington for giving us the results of his investigation and for his helpful comments on our own.

Clinical Application of Demand Pacemakers

EDGAR SOWTON,* M.D., M.R.C.P.

Brit. med. J., 1967, 3, 576–578

Treatment of patients with chronic complete heart block by artificial pacemakers reduces the one-year mortality from approximately 40% to approximately 17% (Sowton, 1967), and with modern techniques and apparatus the morbidity is now low. Parsonnet, Gilbert, and Zucker (1966) reported that after the first few months have been successfully negotiated there is a high probability that one or two uneventful years of stable pacing will follow, and Chardack, Gage, Federico, Schimert, and Greatbatch (1966) claim a better than 90% chance that any individual patient will experience uninterrupted pacing for at least 18 months.

One problem found with patients treated by fixed-rate pacemakers is that sinus rhythm may return, so that competition occurs between natural and artificial pacemakers. This leads to an irregular ventricular rate, palpitations, variations in systemic pressure which occasionally cause symptoms, and the possibility of dangerous arrhythmias provoked by pacemaker stimuli falling in the vulnerable period of the cardiac cycle (Sowton, 1965). These risks are especially important when short-term pacing is carried out in patients with temporary heart block following cardiac infarction (Harris and Bluestone, 1966), because the threshold for arrhythmias is considerably lower than normal and the chances of sinus rhythm returning are considerably higher.

Competition can be avoided by the use of a pacemaker which automatically detects any spontaneous activity and cannot deliver a stimulus until a preset interval has elapsed: such pacemakers are referred to as "demand," "standby," "ventricular-inhibited," or "R-top" units. A pacemaker capable of functioning in this way was described as early as 1956 (Leatham, Cook, and Davies, 1956), and several other external demand units have been described more recently (Nicks, Stening, and Hulme, 1962; Zacouto, 1963; Lemberg, Castellanos, and Berkovits, 1965). Completely implanted demand pacemakers have also been produced, but experience is still limited. Chardack *et al.* (1966) have reported successful results in animal experiments with a Medtronic unit and have implanted similar units in patients (personal communication, 1967). Experience in animals with American Optical miniaturized demand units has been reported by Goetz, Dormandy, and Berkovits (1966), and these units have been used externally in patients; a very few of these pacemakers have also been completely implanted (Berkovits, personal communication, 1967). Most experience under clinical conditions with fully implanted units in patients has probably been gained with the Cordis Ventricor II Standby pacemaker, and Parsonnet, Zucker, Gilbert, and Myers (1966) have reported successful results for periods of over a year. In the present paper some of the clinical experience at the National Heart Hospital and Institute of Cardiology with various types of demand pacemakers is described.

Material and Methods.—The patients were all treated at the National Heart Hospital, initially as inpatients and subsequently followed in the pacemaker clinic. All had had complete heart

---

* Institute of Cardiology and National Heart Hospital, London W.1.

block at some period and all those treated with long-term pacing had a history of Stokes–Adams attacks. The results are best considered in two groups.

Short-term Demand Pacing

Six patients were paced in this way for periods of up to 21 days because of acute block following cardiac infarction, and 15 patients were paced for periods of up to 16 days as a preliminary measure before long-term pacing. Temporary external units have been mainly of two types. Most patients were treated with the commercially available version of the pacemaker designed by Davies (Leatham *et al.*, 1956) in which the E.C.G. input is obtained from ordinary limb leads. More recently a pacemaker designed and built at the Institute of Cardiology has been employed (Norman and Obeyesekera, 1967; Sowton and Norman, 1967). A few patients were also paced with American Optical monitor pacemakers, Model 10750, which incorporate a demand pacemaker.

A large number of measurements of the R wave detected from different transvenous electrodes in the right ventricle have now been made and indicate the amplitude ranges from 2 millivolts to above 30 millivolts under different conditions: even higher values may be found with intramural leads. Since the amplitudes recorded from transvenous electrodes were usually more than 5 millivolts, it is apparent that demand pacemakers should be inhibited by an input signal of about 1.0 millivolts, and this level has proved satisfactory in practice. The rate of rise of the R wave is also important and maximum sensitivity of this pacemaker is achieved at a frequency of 30 cycles/sec.

In all patients competition was completely avoided with each of the three types of external pacemaker. Stable pacing was achieved with each of the three units and there was no detected incidence of failure to pace when the preset time interval following an R wave was exceeded.

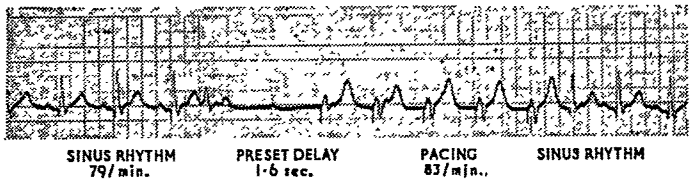

Fig. 1.—On-demand pacing. E.C.G. from a patient with intermittent heart block. After 1.6 seconds asystole pacing automatically starts but the pacemaker is again inhibited by the return of sinus rhythm.

With the Davies pacemaker the interval following an R wave before pacing begins can be adjusted within wide limits, and this interval is independent of the stimulation rate; Fig. 1 illustrates a typical E.C.G. obtained from a patient being paced with this apparatus. There are several features of this pacemaker which are not in keeping with modern techniques, notably the use of a relay in the circuit and the need for skin-contact electrodes to detect the E.C.G., but in our experience it has proved reliable and has been in clinical use until recently.

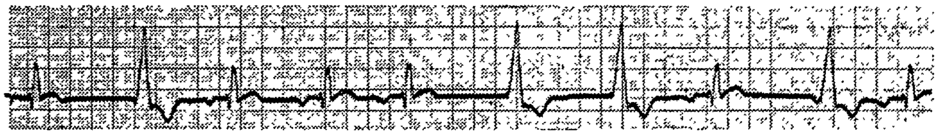

Fig. 3—E.C.G. obtained with Institute of Cardiology demand pacemaker. The pacing stimuli are provided as necessary to prevent the heart rate falling below 60 beats per minute.

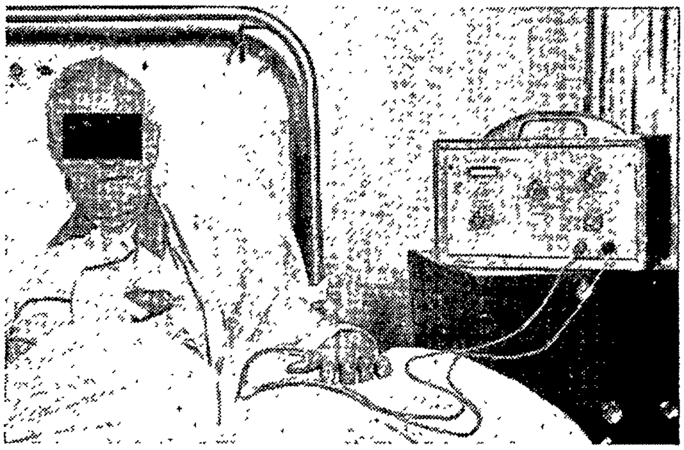
The American Optical demand pacemaker also suffered from the disadvantage that skin-contact E.C.G. electrodes are used to detect spontaneous cardiac activity; movement of the patient may produce artifacts which inhibit the pacemaker, and there is the possibility that displacement of one E.C.G. pick-up electrode resulting in loss of the input signal allows the pacemaker to stimulate and produce competition. Apart from this disadvantage, however, the pacemaker functions satisfactorily.

The Institute of Cardiology demand pacemaker also has a control which adjusts the interval following a spontaneous R wave before pacing impulse is delivered; in this pacemaker this interval is not independent of the pacing rate, so that a simple control determines the minimum ventricular rate below which the pacemaker stimulates. The pacemaker itself (Fig. 2) detects spontaneous cardiac activity via the right ventricular transvenous electrode, which is also used for stimulating, and so avoids the complexity associated with E.C.G. limb leads. The pacemaker has proved extremely simple in use; all that is necessary is for the rate control to be set to the minimum acceptable ventricular rate. If the spontaneous rate is above this level the pacemaker is completely inhibited, but if the spontaneous rate falls below the minimum then the pacemaker provides such stimuli as are necessary to maintain the rate at this minimum level. A typical E.C.G. recorded with this pacemaker is shown in Fig. 3.



[redacted]

Fig. 2.—Institute of Cardiology demand pacemaker in use. Spontaneous cardiac activity is monitored via the same electrode used for pacing.

Long-term Demand Pacing

Seven patients have been treated with fully implanted demand pacemakers for periods of up to 10 months. Two types of implantable demand pacemakers have been used, in each case detecting the spontaneous R wave and stimulating the heart through a right ventricular transvenous electrode. In five cases the pacemaker was a Cordis Ventricor II and in two cases a Medtronic demand pacemaker. Two prototype miniaturized demand pacemakers produced in the medical physics department of the University of Groningen, Holland, were also used in six patients for periods of up to 10 days; these were attached to transvenous electrodes but were carried externally.

Both types of implanted pacemakers have performed satisfactorily and competition has been avoided in all patients. The time interval which must elapse before a stimulus is produced is such that the minimum ventricular rate is 70/min. with the Ventricor II and the Groningen University pacemakers and 60/min. with the Medtronic. Spontaneous sinus rates in these patients occasionally fell below these levels, particularly during sleep, so that paced activity occurred from time to time apart from development of transient heart block. In no case did this result in competition or unpleasant symptoms, though the patients were able to recognize that a particular ventricular beat was paced rather than spontaneous; they were presumably able to make the distinction because of the longer diastolic pause before the first paced beat and also because the paced beat was not preceded by a suitably placed atrial contraction and consequently resulted in a smaller stroke volume and a reduced systolic blood pressure.

During periods of normal sinus rhythm an implanted demand pacemaker is inhibited and normal E.C.G. records therefore give no indication of its presence. The Groningen University model contains a magnetically operated switch which bypasses the demand facility, so that the unit temporarily operates as a conventional fixed-rate pacemaker; application of an external magnet over the pacemaker during E.C.G. recording thus enables a check to be made that the pacemaker is functional. A similar switch is incorporated in some of the American Optical pacemakers used by Goetz *et al.* (1966), but the Cordis and Medtronic units used in these patients do not have this feature. The function of these pacemakers can be checked by manœuvres which slow the heart below the inhibiting rate so that the pacemaker begins to stimulate. Carotid sinus massage was usually adequate in the cases described here, but occassionally a slow injection of 2–10 mg. of Tensilon (edrophonium chloride) was needed; this produced transient slowing and allowed the pacemaker to function for two or three beats. The ideal dose of edrophonium is that which does not quite slow the heart beneath the inhibiting rate for the pacemaker, so that carotid sinus massage can be used in addition to produce an R–R interval which will cause the pacemaker to stimulate.

Discussion

Competition can occur only when significant non-paced cardiac activity is present in a patient with a fixed-rate pacemaker. The major risk of competition is that a pacemaker stimulus falling during the vulnerable period may provoke fatal ventricular fibrillation, and this is most likely to occur when the cardiac threshold for ventricular fibrillation is unduly low. This situation arises when the patient has been given cardiotoxic drugs or has some condition such as acute myocarditis or recent ischaemic damage. The dangers of pacemaker-induced ventricular fibrillation are particularly great after cardiac infarction and in the immediate postoperative phase after the surgical implantation of a pacemaker with attachment of electrodes to the myocardium (Sowton, 1965).

About 25% of all patients with complete heart block who are considered for long-term artificial pacing return to sinus rhythm, at least for short periods, and, as probably 12,500 patients in Britain have chronic complete heart block, there are about 3,000 patients with intermittent block. About two-thirds of these patients may be expected to suffer from Stokes–Adams attacks, and this suggests that artificial pacing is at present indicated for some 8,000 patients in the British Isles, of whom 2,000 should be treated with demand pacemakers. Unfortunately there is no known way to distinguish patients who may return to sinus rhythm once pacing has started, and so there is a case for treating all patients in need of long-term pacing with demand pacemakers as soon as it has been demonstrated that these units are at least as reliable as the simpler fixed-rate type. It should be noted that both atrial-triggered and ventricular-triggered pacemakers also function as demand pacemakers when necessary, but these units are outside the scope of the present paper.

Demand pacemakers are more complicated than simple fixed-rate units, but the implanted types used in the present study are based on the well-proved circuits of the standard Cordis and Medtronic pacemakers. Much of the manufacturing technique and accumulated experience obtained with standard pacemakers has been incorporated in the production of these demand units, in addition to the similarities of much of the circuitry. Since each of the basic pacemakers concerned has a good reputation for reliability, a lifetime of two years for the implantable demand units does not seem unrealistic; however, until actual experience with a large number of units under clinical conditions over this period of time has been obtained, reliability figures must remain hypothetical. Early versions of implantable demand pacemakers have proved unduly sensitive to interference from external electrical fields and several changes in design have been recently introduced to overcome this problem. In none of the cases described here have the patients noted any symptoms related to external interference with pacemaker function, but until wider experience is available it seems wise for implanted demand pacemakers to be used only at hospitals which possess the necessary electronic and medical experience to carry out frequent follow-up checks on the patients. The external demand units currently available have proved very reliable, and it is recommended that they be used in preference to fixed-rate pacemakers in all patients when the threshold for ventricular fibrillation is low.

Summary and Conclusions

Demand pacemakers which do not stimulate during spontaneous cardiac activity are theoretically indicated for all patients treated with short-term pacing and for many patients needing long-term pacing.

A demand pacemaker for short-term pacing has been developed and shown to be clinically reliable. The stimulating electrode is also used as an intracardiac E.C.G. lead to monitor spontaneous activity.

Twenty-one patients have been treated for periods of up to 21 days with external demand pacemakers connected to transvenous right ventricular electrodes.

Seven patients have been treated with fully implanted demand pacemakers for periods of up to 10 months. If these units prove to be reliable over longer periods demand pacemakers should be used for most patients at present treated with conventional fixed-rate units.

Diagnosis of Phenylketonuria (Phenylalanine Hydroxylase Deficiency, Temporary and Permanent)*

J. B. P. STEPHENSON,† M.A., B.M., M.R.C.P., D.C.H.; M. S. McBEAN,‡ M.B., B.S.

Brit. med. J., 1967, 3, 579–581

It is becoming evident that the diagnosis of classical phenylketonuria cannot always be made with certainty before it is judged necessary to prescribe a low-phenylalanine diet (Schneider and Garrard, 1966; Berry and Wright, 1967). If the diagnosis remains uncertain the results of dietary treatment cannot be properly assessed, and there remains the unwelcome possibility that harm may be done by depriving normal children of phenylalanine (Bessman, 1966). This paper reports a striking case of temporary phenylalanine hydroxylase deficiency as an illustration of the problems involved. Later we sought evidence of persisting phenylalanine hydroxylase deficiency in a group of children who have received low-phenylalanine diet. The results of treatment of these children are described elsewhere (McBean and Stephenson, 1967).

Methods

Serum phenylalanine (and tyrosine) was estimated by the snake venom L-amino-acid oxidase method of La Du and Michael (1960) or as modified by Henry (1964), except where indicated in the text. Blood phenylalanine was estimated by the Guthrie test (Guthrie and Susi, 1963). Urine phenylpyruvic acid: standard qualitative ferric chloride and Phenistix tests (Woolf, 1963) graded 1+ to 3+ (slight to strong). Urine orthohydroxyphenylacetic acid: one-dimensional paper chromatography.

Psychometric tests: Griffiths quotients (G.Q.) and Stanford Binet Form L-M intelligence quotients were measured by psychologists of the department of child psychiatry.

Phenylalanine Hydroxylase Deficiency of Early Infancy (Temporary "Phenylketonuria"): Case Report

The patient, date of birth 2 June 1966, was the second male child of unrelated parents. He was delivered by elective caesarean section at term because of previous obstetrical difficulties. Birth weight 3.04 kg. He was fed on National Dried Milk from 3 June and was slightly jaundiced during his first week. Hyperphenylalaninaemia was demonstrated by routine Guthrie test at the age of 5 days.

Investigations.—7 June—Guthrie test: blood phenylalanine 12 mg./100 ml. Urine: tyrosyluria. 20 June—Guthrie test: blood phenylalanine 50 mg./100 ml. 27 June—Urine: orthohydroxyphenylacetic acid present; no tyrosyluria. 30 June—Guthrie test: blood phenylalanine 40 mg./100 ml. 5 July—Urine: $FeCl_3$ 3+; Phenistix 2+. Serum phenylalanine 32.6 mg./100 ml. Serum tyrosine 3.0 mg./100 ml.

On 5 July, when he was clinically normal and weighed 3.4 kg., he was started on low phenylalanine diet (Minafen, cow's milk, Ketovite syrup, and blackcurrant syrup). His progress is summarized in Table I.

After the first month of treatment the serum phenylalanine did not rise above 2 mg./100 ml., but he maintained a steady weight gain. During the second month of treatment he suffered a series of convulsions (not hypoglycaemic) and developed hypochromic anaemia with normal serum iron. Despite progressive increase in phenylalanine intake up to 116 mg./kg./day his serum phenylalanine did not rise to 3 mg./100 ml. The diagnosis of phenylketonuria was therefore questioned, and normal milk diet was offered after four months of restricted phenylalanine. Nonfasting serum phenylalanine levels rose only slightly above normal, but orthohydroxyphenylacetic acid was detected in the urine at this time. During the following three months no phenylpyruvic acid was detected in the urine.

TABLE I.—*Progress of Temporary "Phenylketonuric" on Low-phenylalanine Diet*

Age in months	Month of Diet	Phenylalanine Intake/Day mg.	Phenylalanine Intake/Day mg./kg.	Serum Phenylalanine (mg./100 ml.)	Fe Cl_3	OHPAA*	G.Q.†	Clinical Impression
1		1,000	300	32·6	+	+		Normal
2	1	280	64	0·0–2·8				
3	2	350	60	0·5–1·0				Convulsions. Anaemia
4	3	470	70–78	0·0–2·0				
5	4	470–870	64–116	1·8–2·0				
6		1,500	200	3·1–4·0		+	62	
7		Unrestricted diet		0·8 (fasting)			72	Plump. Sociable. Probably retarded

* Orthohydroxyphenylacetic acid.
† Griffiths quotient.

On 20 January 1967 an oral phenylalanine tolerance test was carried out, with 100 mg. of L-phenylalanine per kg. body weight, administered by gavage (Table II). Serum estimations were made in duplicate.

TABLE II.—*Phenylalanine Tolerance Test on Patient Aged* 33 *Weeks.* L-*phenylalanine* 100 *mg./kg. by Gavage at Zero Time*

Time	Serum Phenylalanine mg./100 ml.)	Serum Tyrosine (mg./100 ml.)	Urine OHPAA
Fasting	0·8	1·1	None
1 hour	3·4	1·2	
2 hours	3·6	2·5	
3 "	2·3	1·8	Very faint trace
4 "	2·1	1·4	

Comment

The fasting serum phenylalanine was unequivocally normal and the rise in serum tyrosine after phenylalanine loading confirmed the presence of phenylalanine hydroxylase activity. The diagnosis of classical phenylketonuria was therefore excluded.

At the time of writing the child was 8 months old, well nourished, and socially responsive, but the clinical impression of a degree of psychomotor retardation was supported by psychometric tests (Table I).

The child's parents have normal serum phenylalanine levels, but their genotype has not yet been established.

Reassessment of Presumptive Phenylketonurics

The recognition of temporary "phenylketonuria" prompted a review of the diagnosis of other presumptive phenylketonurics.

† Registrar in Medical Paediatrics, Royal Hospital for Sick Children, Glasgow C.4.
‡ Research Assistant, Royal Hospital for Sick Children, Glasgow C.4.

In this report we include only those children who have received low-phenylalanine diet and have been studied until after their first birthday (McBean and Stephenson, 1967). Because of this minimum follow-up period cases detected by mass neonatal screening by the Guthrie test are not included, nor are infants who have removed to other districts. Table III shows the clinical features of those infants detected in the first three months of life.

TABLE III.—*Infants Detected in First Three Months: Clinical Features*

Case No.	Sib. with PKU	Clinical Features Before Treatment					I.Q. <80 After 1 Year (lowest)

7†			+		+		
8†				+			

* Presented with symptoms.
† Detected by napkin-Phenistix screening test.
PKU ≙ Phenylketouria.

Partington (1961) has stressed the frequency of early symptoms in phenylketonuria (vomiting, feeding problems, colic, ? pyloric stenosis, irritability, eczema and other rashes, suspected retardation, and, later, seizures). It is evident that none are specific, but it may be that such symptoms will be found to be more frequent in true phenylketonurics. Certainly in two of these patients the symptoms were valuable in bringing the child to hospital at an early age. Routine urine testing then revealed the diagnosis. Case 4 was detected in this way in January 1961, after pyloromyotomy (for marked hypertrophic pyloric stenosis). The other infants were detected either because an older sibling was known to have classical phenylketonuria or through routine napkin-Phenistix testing by the local health authorities (Stephenson and McBean, 1967).

Table IV gives some of the biochemical findings. The degree of positivity of the Phenistix reaction on fresh urine is recorded in preference to the ferric chloride reaction because it is more easily defined. In all cases the unacidified urine also gave a typical green colour with aqueous ferric chloride (Woolf, 1963).

TABLE IV.—*Infants Detected in First Three Months: Biochemical Features*

Case No.	Age at Test (days)	Biochemical Features Before Treatment		Highest Serum Phenylalanine After One Year (mg./100 ml.)
		Urine Phenistix	Serum Phenylalanine (mg./100 ml.)	
1	11	+ + +	30·0*	25·2
2	20	+ + +	65·0	50§

* Chromatographic method (Berry, 1957).
† Five days after pyloromyotomy.
‡ Four days after diet started.
§ Guthrie inhibition assay.

It is evident that all these children, including those who were asymptomatic, have a persisting tendency to hyperphenylalaninaemia. In three (Cases 1, 6, and 7) dietary control has been excellent since early infancy, but at ages 3½, 4½, and 2 years, respectively, hyperphenylalaninaemia was induced by feeding a normal phenylalanine diet for a few days. (Complan was substituted for Cymogran for this test. The use of ordinary foodstuffs for such a trial is contraindicated in case the phenylketonuric child loses his taste for the low-phenylalanine diet.) In the remaining five cases[1] the high serum phenylalanine levels resulted from dietary indiscretions (excess phenylalanine intake).

The older patients (Cases 11–33), detected at age 6 months to 10 years, all gave evidence of permanent enzyme defect. In Cases 11–30 this was demonstrated by hyperphenylalaninaemia over the age of 1 year. Three earlier cases (Nos. 31–33), with severe mental retardation, did not have serum phenylalanine estimations, but two of them had typical phenylketonuric siblings, and the urine of the third contained phenylpyruvic acid, which disappeared during low-phenylalanine diet. In all cases the urine gave a typical positive reaction with ferric chloride, and the initial I.Q. was always below 80. Table V shows the distribution of serum phenylalanine levels, which tend to be lower than in the young infants.

TABLE V.—*Distribution of Serum Phenylalanine Levels in Phenylketonurics Diagnosed Age 6 Months to 10 Years (Cases 11–33)*

Serum Phenylalanine	No. of Children
Under 20 mg./100 ml.	1*
20— „	5
30— „	9
40— „	2
50— „	3
Not known	3

* 18 mg./100 ml. at age 10½ years.

No attempt was made to assess the likely genotype of these children by testing their parents, but the course in all cases suggests the diagnosis of homozygous phenylketonuria.

Discussion

When infant screening was introduced it was assumed that the new-found phenylketonurics would be differentiated from the remainder of the population as sharply as was the case in older children and adults. There is now increasing concern about the validity of this assumption (Bessman, 1966; Schneider and Garrard, 1966; Perry *et al.*, 1967; Berry and Wright, 1967). In the first place, it may be that the biochemical abnormalities of heterozygotes for the usual gene of phenylketonuria overlap with those found in (homozygous) phenylketonurics, making definitive diagnosis in the asymptomatic neonate impossible (Schneider and Garrard, 1966). Secondly, and perhaps more important, there might be delayed maturation of the enzyme phenylalanine hydroxylase even in infants of normal genotype. We have presented evidence to show that the infant whose case is described above had just this disorder. Until treatment was started in the fifth week of life he had the biochemical syndrome of severe phenylalanine hydroxylase deficiency (serum phenylalanine over 30 mg./100 ml., with urine phenylpyruvic acid and orthohydroxyphenylacetic acid), but by the age of 5 months his phenylalanine tolerance was normal. Indeed, the results of his fasting serum estimations (Perry *et al.*, 1967) and tolerance test (Hsia *et al.*, 1956) suggest that he is unlikely even to be heterozygous for the usual gene of phenylketonuria, irrespective of the probable genotype of his parents.

We may speculate briefly on the probable sequence of events in this case. Originally he had tyrosyluria, and could be classed as the type 2 phenylalaninaemia of Berry and Wright (1967), with presumptive deficiency of both phenylalanine hydroxylase and parahydroxyphenylpyruvic oxidase systems. The two enzyme systems then matured at different rates, parahydroxyphenylpyruvic oxidase rising to normal some weeks before phenylalanine hydroxylase. In our reassessment of presumptive phenylketonurics we have found no further cases of temporary enzyme deficiency, but the report of the Cincinnati conference on the treatment of phenylketonuria (Berry and Wright, 1967) suggests that milder examples may not be rare.

---

[1] Cases 9 and 10 are not described: follow-up details are not available.

A probable instance was reported by Moncrieff and Wilkinson (1961), though at the time of diagnosis the method for serum phenylalanine was not yet entirely satisfactory.

The effect of a low-phenylalanine diet on our case of temporary phenylalanine hydroxylase deficiency is of particular importance. Despite a normal gain in weight throughout treatment, and a phenylalanine intake never below 60 mg./kg./day, serum phenylalanine levels remained persistently low. There is only limited information on the phenylalanine requirements of normal infants, but Snyderman *et al.* (1955) suggest that less than 90 mg./kg./day might be unsafe. This figure was derived in part from observations on the weight gain of infants on differing phenylalanine intakes. However, it may be possible, as in the case described above, for normal weight gain to occur despite phenylalanine deficiency. If so, the optimum phenylalanine intake for a normal child may be much higher than 90 mg./kg./day. The particular concern is that harm might be done to the developing brain by phenylalanine deprivation (Bessman, 1966). There is suggestive evidence that general undernutrition during infancy will inhibit subsequent intellectual development (Stoch and Smythe, 1963), and isolated phenylalanine deficiency might do likewise. This is supported by the delayed psychomotor development in our case and in those reported by Rouse (1966) and Moncrieff and Wilkinson (1961). A fall in developmental quotient may also be seen in phenylalanine-deficient phenylketonuric infants (Brimblecombe *et al.,* 1961, and personal observations). In both the normal and phenylketonuric infants there is a tendency for the developmental quotient to rise after the phenylalanine deficiency is corrected, but the possibility remains that some damage may have been done.

In this somewhat disturbing situation, with no satisfactory criteria for making the diagnosis of phenylketonuria in early infancy, and with the danger of harming normal children by phenylalanine deprivation, some would advocate that the low-phenylalanine diet should not be given (Bessman, 1966). We would strongly oppose this, for the undoubted benefits of treating true phenylketonurics from early infancy would be lost (McBean and Stephenson, 1967). Well-controlled dietary treatment might indeed prevent brain damage even in temporary "phenylketonurics" if transient hyperphenylalaninaemia (and its biochemical consequences) is harmful. Rather one should concentrate on avoiding phenylalanine deficiency, using the strict criteria of Umbarger *et al.* (1965), whose well-controlled patients have a serum phenylalanine of 3 mg./100 ml. or more, no urine orthohydroxylphenylacetic acid, and urine phenylalanine 25–150 μg./ml.

Perhaps initial tyrosyluria may be a common accompaniment of temporary phenylalanine hydroxylase deficiency, as in our case, and may serve as a warning. If during treatment a serum phenylalanine concentration of 3 mg./100 ml. is difficult to sustain, or frequent changes in phenylalanine intake are found to be unnecessary (Umbarger *et al.,* 1965), or one of the parents can be shown not to be heterozygous (Hsia *et al.,* 1956 ; Perry *et al.,* 1967 ; Woolf *et al.,* 1967), then the diagnosis of phenylketonuria must be reconsidered. At the present time we would recommend a diagnostic trial of normal milk intake for young infants, and a substitution of Complan for Cymogran in older children, for a maximum of 10 days, with biochemical monitoring. In conclusion, we emphasize that the diagnostic difficulties and the consequences of error are so great that all suspected cases of phenylketonuria should be referred to special centres.

Summary

Temporary phenylalanine hydroxylase deficiency is described in a child thought to be genetically normal on the basis of his later response to phenylalanine loading. The condition is indistinguishable from phenylketonuria in early infancy, and might remain unrecognized during low-phenylalanine diet. Because it is possible that mental subnormality may result from clinically mild phenylalanine deficiency in such infants, the diagnosis of phenylketonuria should be re-examined when a serum phenylalanine concentration of 3 mg./100 ml. is difficult to sustain or where the genotype of one of the parents is in doubt.

Thirty-one children who had received low-phenylalanine diet were reassessed. Evidence of phenylalanine hydroxylase deficiency persisting beyond the first birthday was obtained in all.

We thank Professor J. H. Hutchison and Dr. R. A. Shanks for advice and criticism ; Dr. L. I. Woolf for orthohydroxyphenylacetic acid estimations ; and Dr. J. S. Stevenson for making available the results of Guthrie tests. Psychological testing was carried out by Mrs. Peggy Emerson and Miss Valerie Labrum.

Phenylketonuria: A Reassessment of Mass Infant Screening by Napkin Test[*]

J. B. P. STEPHENSON,[†] M.A., B.M., M.R.C.P., D.C.H.; M. S. McBEAN,[‡] M.B., B.S.

Brit. med. J., 1967, **3**, 582

Most local health authorities in Great Britain have used the Phenistix test on wet napkins or diapers (napkin-Phenistix test) to screen all young infants for phenylketonuria (Centerwall *et al.*, 1963). This test is a sensitive and reliable method of detecting phenylpyruvic aciduria (Gibbs and Woolf, 1959; Woolf, 1963), which is an early sign of true phenylketonuria (Allen *et al.*, 1964; Berry and Wright, 1967). Some practical difficulties have been emphasized by Hudson and Ireland (1959), but information is lacking on the effectiveness of the napkin test in mass detection programmes. In the Birmingham screening survey (Boyd, 1961) one case was found out of 18,981 tested, which was thought to be adequate, assuming a regional incidence of one in 20,000 births. In Edinburgh a similar incidence was predicted, but the one expected case was missed (Farquhar *et al.*, 1962).

Present Study

With the assistance of the seven local health authorities involved we have investigated 15 true phenylketonurics (Stephenson and McBean, 1967) who were born when screening programmes were in operation, between 1960 and 1965. Siblings of previously known phenylketonurics have been excluded from the study. The dates and results of napkin tests were determined from the Child Welfare record cards. The details are given in Table I.

TABLE I.—*Phenylketonurics Born into Napkin-Phenistix Screening Programmes*

Phenistix Result		No. of Patients
Positive	Under 3 months old	4 (youngest aged 53 days)
	Over 3 months old	2 (1 aged 9 months; I.Q. 47)
Negative		6 (2 tested under 3 weeks only: 1 in hospital aged 6 weeks)
Not tested		3 (1 ?negative aged 42 days: no record made. 1 only at home aged 5–11 weeks)
Total		15

TABLE II.—*Results of 16 Napkin-Phenistix Tests on 12 Phenylketonurics, Related to Age of Testing*

Age (weeks)	No. of Tests	Results	
		Positive	Negative
1–3	6	–	6
5–10	4	1	3
>10	6	5	1

It is apparent from Table II that all napkin-Phenistix tests in the first three weeks of life were negative, but much more serious is the fact that even in the age group 5–10 weeks only one of four tests was positive.

When the four patients with negative napkin-Phenistix tests over the age of 5 weeks were finally diagnosed they were all obviously affected, and in each case the urine reacted strongly with ferric chloride. Table III shows the serum phenylalanine levels and I.Q. at the time of diagnosis.

TABLE III.—*Missed Phenylketonurics: Finding on Diagnosis*

Age at Negative Napkin Test	Age at Diagnosis (months)	Serum Phenylalanine (mg./100 ml.)*	I.Q.
5 weeks 2 days	9	26	43 (Cattell)
7 „ 1 day	3	70	51 (Griffiths)
9 „ 3 days	25	42	46 „
6 months	24	51	50 „

* La Du and Michael (1960).

Conclusions

This investigation shows that the napkin-Phenistix test in a mass screening programme is not an efficient tool for the early detection of classical phenylketonuria. Even the detection rate of 27% under the age of 3 months is probably optimistic, because cases missed towards the end of the period—for example, 1965—may not yet be obviously retarded, and most of the children at risk have not entered school.

A great deal of enthusiasm, hard work, and organizational skill have gone into the execution of these mass screening programmes, but the time has come for such energies to be directed towards more efficient methods of detection.

This study would have been impossible without the co-operation of the medical officers of the Health Departments of Airdrie, Clackmannan, Clydebank, Falkirk, Glasgow, Motherwell, Paisley, Ealing, and Londonderry. We thank Professor J. H. Hutchison and Dr. R. A. Shanks for encouragement and criticism.

Detection of Incompetent Perforating Veins by Venography at Operation

JULIAN TOWNSEND,* M.B., B.CHIR., F.R.C.S. ; HUGH JONES,† M.S., F.R.C.S.
J. EDMUND WILLIAMS,‡ B.SC., M.R.C.P.ED., F.F.R.

Brit. med. J., 1967, 3, 583–585

All types of varicose veins can be treated successfully by a radical stripping operation in which the whole system of diseased veins and related perforating veins is removed (Myers, 1957 ; Arenander, 1960 ; Sherman, 1964). Simple procedures such as high ligation, with or without stripping of the main saphenous trunk, though widely practised, are much less successful, even in the early and uncomplicated case. Great saphenous incompetence is usually obvious, and can be convincingly demonstrated by the Brodie–Trendelenburg test. Femoro-saphenous reflux fills the superficial veins with blood at a low pressure only (Cockett, 1956).

Incompetent perforating veins, however, are easy to overlook, and their presence cannot be excluded with certainty by any clinical test. They are present in 90% of cases (Sherman, 1949), and are especially important as a cause of varices which persist or recur after operation (Mathiesen, 1953 ; Lofgren, Myers and Webb, 1956 ; and many others), and as the cause of ulcers. Cockett and Jones (1953) showed that the venous drainage of the lower part of the leg is through short perforating veins to the deep vessels, and only indirectly through the saphenous systems. Thus in this area any superficial venous disease is likely to stem from the perforating vessels, and it is here in the "gaiter-area" that the high intermittent pressures in the deep veins can be transmitted to the surface through incompetent perforating veins, leading to ulceration (Arnoldi, 1966). "Varicose ulceration" due solely to incompetence of superficial veins does not occur, for incompetent perforating veins can be found in association with every venous ulcer (Sarjeant, 1964 ; Arnoldi, 1966 ; Haeger, 1966). It is true that saphenous incompetence may be a contributory cause of ulceration and that ulcers may be healed by removal of the saphenous vein, but the effect is unpredictable and healing often only temporary (Moore, 1957 ; Haeger, personal communication, 1966).

It is sometimes thought that stripping out the saphenous trunk destroys the perforating veins, but Sherman (1949) has shown that about one-half of all perforating veins, and most of the incompetent ones, are not directly connected with the saphenous trunks. Radical stripping operations, though repeatedly shown to be very effective, are not practised by the majority of surgeons, who perhaps feel that the time and trouble required and the trauma to the patient are not justified even by a reasonably certain cure. Another prevalent view, that varicosis is a progressive condition essentially unsuited to radical cure, has some basis in fact, but is founded more on a practice of inadequate diagnosis followed by inadequate surgery.

Preoperative diagnosis of incompetent perforating veins is difficult. Various clinical signs are described but none is reliable. Surgeons experienced in venous disease commonly find at operation incompetent perforating veins which they have not detected previously. The lesser operations which are commonly practised often leave incompetent perforating veins intact, with the attendant risk of persistent or recurrent varices and ulcers. If it were possible to locate incompetent perforating veins accurately and confidently it is probable that they would be ligated more frequently and with greater economy than is now usual, and with improved results. For this reason some methods of venography have been examined and the findings assessed by surgical exploration. A technique of venography has been evolved which with practice is easy to perform, easy to interpret, and reliable.

It is widely held that there is no place for routine venography in the treatment of varicose veins. This is not our experience. Accurate diagnosis leads to precise surgery, and may obviate the need for a formal operation, such as that of Cockett and Jones (1953), in which an incision half the length of the tibia is sometimes made in order to ligate a single incompetent perforating vein, or even without finding one at all (Dodd and Cockett, 1956).

The results of venography were compared with a number of common physical signs, the most useful of which was found to be palpation of fascial defects. We agree with many other writers that the fascial defect lies not in the deep fascia, where a hole is rarely palpable, but in the superficial fascia, where a varix lies at the superficial end of an incompetent perforating vein. All fascial defects and all incompetent perforating veins shown by venography were exposed at operation, and the competence of any perforating vein was tested by the bleed-back test of Turner Warwick (1931).

Method

Before operation the position of the dilated veins was marked on the skin. The leg was then palpated, and all fascial defects were marked, and then labelled with a lead shot secured by adhesive plaster.

The anaesthetized patient was placed on a radiolucent table top, with a 5-degree foot-down tilt. Under aseptic conditions a sternal-puncture needle was inserted horizontally deep into the lower end of the tibia in the position shown in Fig. 1. Injection of a little isotonic saline and the withdrawal of a stream of blood into the syringe confirmed that the needle was correctly placed. Difficulty in making the injection was due to the needle being either too low or not far enough in. With the leg in the anatomical position the *x*-ray tube and film were placed to take an anteroposterior view, with the ankle joint just included at the lower end.

The veins were drained by raising the leg to 30 degrees for 30 seconds. Omission of this step led to excessive dilution of the opaque medium. The leg was lowered and 20 ml. of warm 45% Hypaque (sodium diatrizoate) was injected in 30 seconds. As soon as injection was completed the foot was replaced in the anatomical position and the film exposed. A second film was placed to include the femoral condyles and exposed immediately after gently flexing the foot up and down. The leg was again raised to ensure that no medium remained stagnant in the veins, and any possible risk of thrombosis was avoided.

Interpretation

Incompetence is almost certain when a perforating vein is seen with localized filling of veins at its superficial end, for then

† Consultant Surgeon.
‡ Consultant Radiologist.
Varicose Vein Clinic, Cardiff Royal Infirmary.

flow must have been outward (Fig. 2, a, b, and c). When several incompetent perforating veins are present there may be dense filling of some superficial veins, and it is then impossible to say whether a given perforator has filled from within or without. An abnormal perforator is enlarged and may be irregular or tortuous superficially ; there may be localized dilatation of the deep or superficial veins at either end of it. A localized superficial varix is a strong indication of the presence of an incompetent perforating vein (Fig. 3, b).

Any medial perforator which fills from within is incompetent, but lateral muscular perforators, which are often large and double, may fill from within yet be competent unless there is also definite filling of overlying superficial veins (Fig. 2, c and d).

When an incompetent perforating vein has been recognized on the *x*-ray film it is not always easy to find the corresponding site on the leg, but by reference to the lead markers it is possible to gauge the level with great accuracy. This information, in conjunction with the skin-markings of varices and fascial defects, is interpreted with reference to the anatomy of the perforating veins, good accounts of which have been given by Sherman (1949) and Sarjeant (1964), and usually allows accurate location of the site of incompetence.

When the radiographic information is considered on its own it is likely to be less valuable than when combined with clinical signs. For this reason it is advised that the surgeon should co-operate in the interpretation of the venograms, especially as he has the opportunity to examine the veins at operation, and so correlate the clinical and radiographic signs with the actual state of the veins.

Anteroposterior views only were used, and proved adequate, firstly because nearly all the clinically important perforating veins lie in the tibial and peroneal groups, which show best in this projection, and secondly because the incompetent posterior muscular perforating veins are easy to recognize clinically.

The method of intraosseous venography does not invariably show the deep veins, and reliable information on these can only be obtained by other techniques.

Results

So far 31 patients have been treated and 46 legs operated on. It is believed that few incompetent perforating veins remained undiscovered, because during the course of the operations many perforating veins were seen by chance at sites other than those under investigation, and all these additional perforating veins appeared normal. Those tested by the method of Turner Warwick (1931) were competent.

The clinical, venographic, and operative findings are shown in the Table.

Results of Exploration at All Sites Where Incompetent Perforating Veins (I.P.V.) Were Diagnosed by Clinical Signs and by Venography

Preoperative Diagnosis		Findings on Exploration		
Diagnostic Procedure Leading to Exploration	No. of Sites	Diagnosis Confirmed (I.P.V. Found)	Diagnosis not Confirmed (No I.P.V. Found)	I.P.V. Found Elsewhere
Clinical signs	112	72	40	32
Venography	109	96	13	8
Total (clinical signs, venography, or both)	156	104	52	Nil

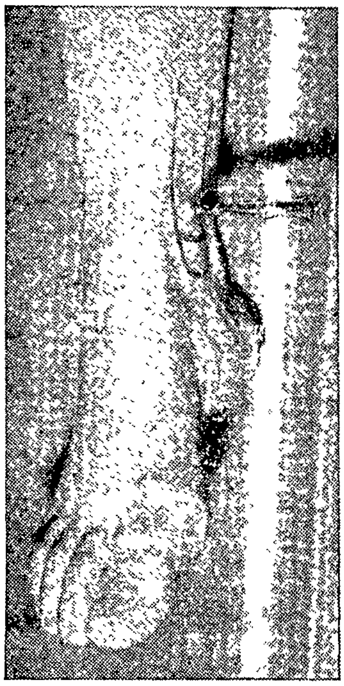

FIG. 1.—The needle is inserted just above the base of the medial malleolus and pushed well in. (A Salah needle, gauge 15 or 12, was used for most of these venograms, but several other types were used.)

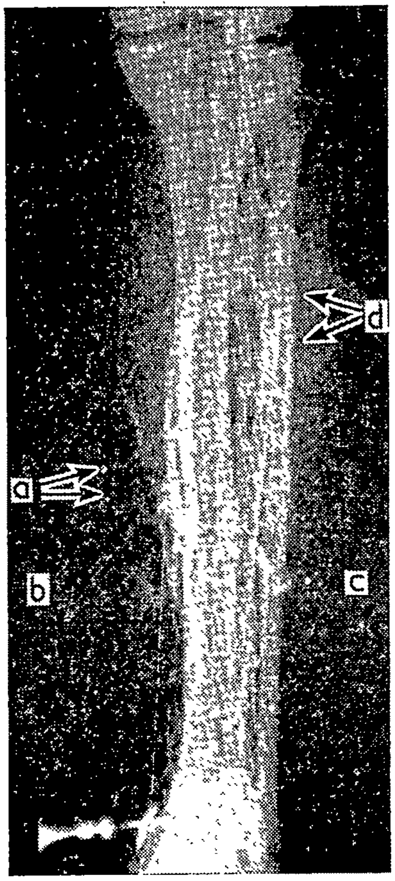

FIG. 2.—a, b, and c, Incompetent perforating veins with filling of overlying superficial veins. d, Paired peroneal muscular veins filling from the deep veins. Note the paired deep calf veins (normal) and paired popliteal veins (variation).

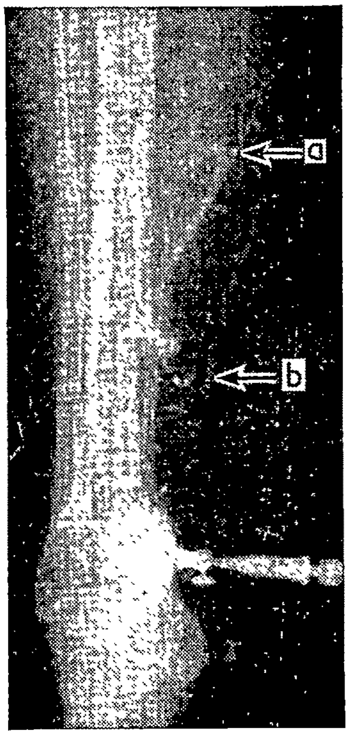

FIG. 3.—a, Fascial defect (with lead marker) seen to be due to superficial varix only. b, Incompetent perforating vein with overlying superficial varix. Note the distance between the fascial defect and the perforating vein.

A total of 104 incompetent perforating veins were found at operation. Clinical signs had detected 72 (69%) of these and missed 32 (31%). A further 40 explorations were made on clinical grounds without any incompetent perforating vein being found. Venograms had detected 96 (92%) of the 104 incompetent perforating veins, but had failed to detect the remaining eight. Another 13 sites were explored because of venographic signs, but no incompetent perforating veins were found.

The distribution of all the incompetent perforating veins found is shown in Fig. 4 and corresponds well with that found by Sherman (1949) in nearly a thousand radical operations.

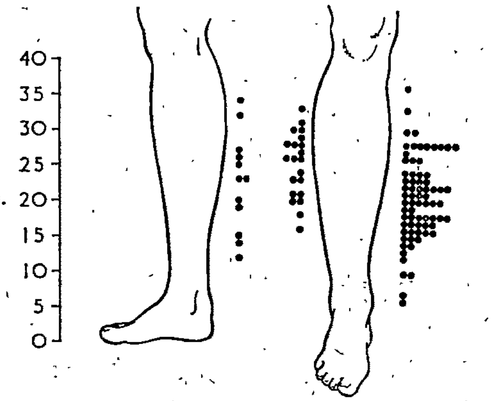

FIG. 4.—Distribution of incompetent perforating veins in 46 legs with varices. The medial group are those lying behind the tibia, the lateral group are closely related to the fibula. The remainder were posterior muscular perforating veins; all of these were detected clinically, but three were not detected by venography. There were no incompetent anterior perforating veins in this group of patients.

Discussion

Intraosseous venograms are easy to interpret because of the lack of superficial venous filling (Fig. 5). We have found the calcaneum a little less satisfactory in this respect than the malleoli. We have also used the lateral malleolus, as recommended by Cockett (1953), but have found that demonstration of the important perforating veins medial to the lower third of the tibia was not always reliable. Injection into the lower tibia has proved better: it is a little more difficult to insert the needle, but satisfactory injection can always be made and films of diagnostic value obtained.

The method described is simple to perform and requires few extra facilities. The whole examination should add less than 10 minutes to the operating-time for bilateral varices. There have been no complications. The precise information obtained is of value in two ways: firstly, the operation can be more comprehensive than when reliance is placed on clinical tests alone, and, secondly, the operation can be planned to minimize the number and extent of the incisions. The technique and interpretation are likely to give difficulty if venography is used only as an occasional procedure to investigate the complex problem, but they become simple with practice.

Even in "primary" long saphenous varices an incompetent perforating vein is often present and may be surprisingly large. Such a vein can easily be ligated through a small incision over it. A variety of cases have been treated, ranging from simple "primary" varices to post-thrombotic ulcers. Venography proved helpful in 36 of the 46 legs and in all types of case. Despite the fact that excision of varices was not practised, very few postoperative injections have been required.

Summary

Incompetent perforating veins are usually present with varicose veins. They are responsible for most of the complications and for some recurrences. They should be obliterated.

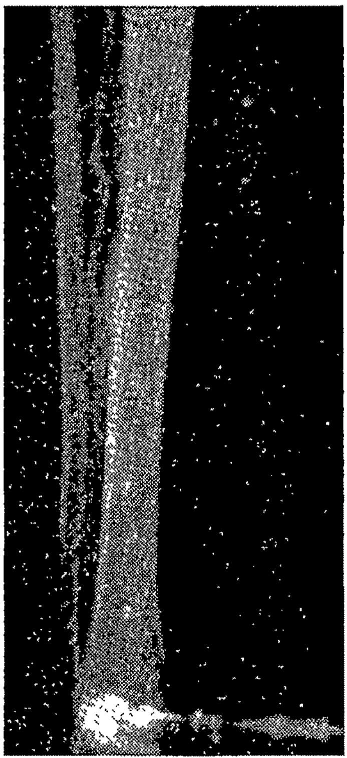

FIG. 5.—No incompetent perforating veins present. The dye passes from the bone marrow to the deep veins, but none escapes into the superficial veins.

A method of operative venography is described which has proved reliable in the detection of incompetent perforating veins and much superior to clinical examination alone.

The information obtained made possible a more comprehensive and more precise operation in three out of every four legs treated.

We thank the radiographers of Cardiff Royal Infirmary and Llandough Hospital for their willing assistance, and Miss Kathleen Davies for patient secretarial help.

Requests for reprints should be addressed to Mr. J. Townsend, c/o the Secretary, Varicose Vein Clinic, Royal Infirmary, Cardiff.

Acute Myocardial Infarction in Pregnancy

E. FLETCHER,* M.D., F.R.C.P.; E. W. KNOX,* M.D., M.R.C.P.I.
P. MORTON,* M.D., M.R.C.P.ED.

Brit. med. J., 1967, 3, 586–588

Obstructive coronary artery disease is the rarest form of primary organic heart disease encountered during pregnancy. Myocardial infarction occurring during pregnancy was confirmed for the first time at necropsy by Katz (1921). The first case of recurrent myocardial infarction during pregnancy and labour, with electrocardiographic evidence, was published in 1935 by Reis and Frankenthal. Since then a few further case reports have been published by various authors. Bedford (1964) was able to collect only four cases in the British literature, to which he added one of his own. In a recent review Watson *et al.* (1960) collected 23 authentic cases of myocardial infarction during pregnancy or labour. To this number may be added the case of Magner (1961), that of Bedford referred to above, and the five cases described in this paper, a total of 30 in the world literature.

This paper presents the clinical and electrocardiographic data of five women who sustained major episodes of acute myocardial infarction while pregnant. During the period 1 January 1955 to 31 December 1966 at least 40,000 patients attended the antenatal clinics of the Belfast City Hospital. The five patients already mentioned were selected from approximately 800 pregnant women referred to the cardiac department for assessment. They were all multigravidae, with an age range of 36–41 years. There was no maternal mortality in connexion with the pregnancies or puerperia. All but one (Case 5) pro-

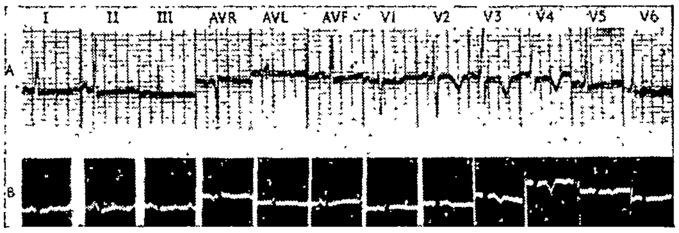

FIG. 1.—Case 1. A (29th week of 4th pregnancy). Sinus rhythm. Abnormal S-T segment and T-wave displacement with grossly abnormal T waves, most pronounced in leads V2–V6. The tracing is consistent with the acute phase of anteroseptal ischaemia or infarction. B (16 days after A). In the interval between the tracings there has been some correction of repolarization, but the underlying myocardium remains abnormal.

Summary of Relevant Data in Five Cases

Case No.	Age	No. of Pregnancies	Week of Onset	Symptoms	Preceding Hypertension	Pre-eclamptic Toxaemia	Biochemical Findings				Follow-up
							S.G.O.T. (units)	S.G.P.T. (units)	Cholesterol (mg./100 ml.)	β-Lipoproteins (mm.)	
1	38	4	29	Dyspnoea for one week, followed by severe crushing retrosternal pain radiating to neck and left arm. Pain lasted 1½ hours	No	No	150		280		Normal delivery of living child at 38 weeks. Puerperium uneventful. Persistent angina of effort over 7 years. Remains normotensive
2	36	7	30	No symptoms referable to C.V.S. before onset of this pregnancy. Sudden attack of severe substernal pain lasting several hours. Pain accompanied by sweating and dyspnoea	No	Yes. All previous 6 pregnancies resulted in stillbirths before 7th month on account of hypertension oedema and albuminuria	50		280		Living child by caesarean section at 40 weeks. Puerperium uneventful. Persistent angina of effort over 2 years 3 months Sudden death after severe episode of retrosternal pain. E.C.G. a few hours before death confirmed a fresh extensive myocardial infarction
3	36	4	32	Epigastric discomfort on exertion relieved by rest, followed 10 days later by crushing retrosternal pain radiating to both arms. Pain awakened patient from sleep and lasted 3 hours	No	No	95		280		Normal delivery of living child at 40 weeks. Puerperium uneventful. No recurrence of ischaemic cardiac pain during 2-year follow-up
4	38	2	30	Dyspnoea for 2 weeks followed by sudden onset of retrosternal tightness associated with flatulence	No	No	50				Normal delivery of living child at 38 weeks. Puerperium uneventful. No follow-up after discharge
5	41	22	13	2-year history of angina of effort before onset of this pregnancy. Awakened from sleep with crushing retrosternal pain radiating to left arm. Pain lasted five hours	Yes	Yes (onset at 28 weeks)	107	32	412	4·2	Intrauterine death at 29 weeks. Normal delivery of macerated foetus at 33 weeks. Puerperium uneventful. Still angina of effort during three-month follow-up

duced healthy children. The cause of the single foetal death was severe pre-eclamptic toxaemia. It was not related to the cardiac status of the mother. Two patients (Cases 2 and 5) had severe pre-eclamptic toxaemia of pregnancy, and this might be a contributing factor for the occurrence of coronary atherosclerosis. The other three women had no general medical condition likely to predispose them to coronary artery disease. The relevant clinical obstetric and biochemical data for each patient are summarized in the Table. Serial electrocardiograms were recorded in each case, and these are shown in Figs. 1–5.

Discussion

In a review of 45 cases of coronary artery disease associated with pregnancy by Mendelson (1960) 19 had systemic hypertension, 9 had cardiovascular syphilis, and 2 had diabetes mellitus. Two of our patients (Cases 2 and 5) had a systemic disease likely to predispose to coronary atherosclerosis—that is, a long history of recurrent toxaemia of pregnancy with hypertension. The underlying disorder in all five cases appears to have been coronary atherosclerosis. In all but one of them the acute infarctions occurred in the third trimester, when the oxygen demand of the tissues is increased and the work load of the heart is at its maximum. During pregnancy the blood chemistry alters significantly; the total cholesterol increases and more is attached to the beta-lipoproteins. The pattern resembles that found in men with ischaemic heart disease (Oliver and Boyd, 1955). These changes are maximal about the thirty-third week, and they take place in spite of the great increase in circulating oestrogens, known effective agents in restoring the non-atherosclerotic plasma lipid pattern (Barr, 1953).

The dynamic factors and biochemical changes referred to above may have predisposed some of our patients to coronary occlusion at the critical weeks of gestation, on the assumption that they already suffered from coronary atherosclerosis. They are not, however, the whole answer, since one patient (Case 5)

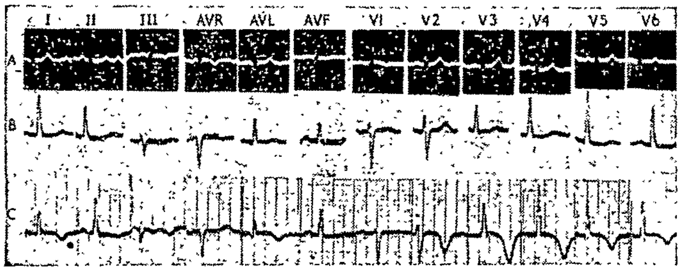

Fig. 2.—Case 2. A (20th week of 7th pregnancy). Normal tracing. B (10 weeks after A). Sinus rhythm. Abnormal S-T segment depression in leads I, II, and V4 V6. An abnormal tracing when compared with A. C (two weeks after B). Abnormal S–T segment displacement in the limb leads with increased polarity of T waves in leads I, AVL, and V2–V6. The tracing is consistent with recent anterolateral infarction.

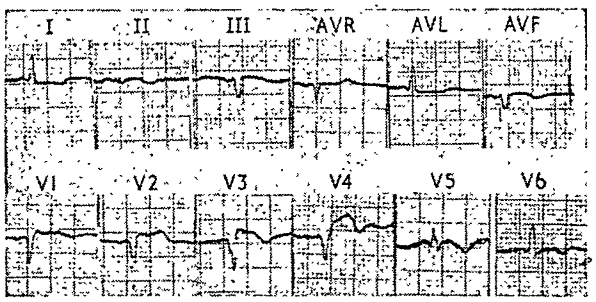

Fig. 3.—Case 3 (32nd week of 4th pregnancy). Sinus rhythm. Abnormal Q–S deflections in leads V1–V4. S–T segment and T-wave displacement upwards due to injury current in these leads and also in leads II, III, and AVF. The tracing is consistent with acute myocardial infarction.

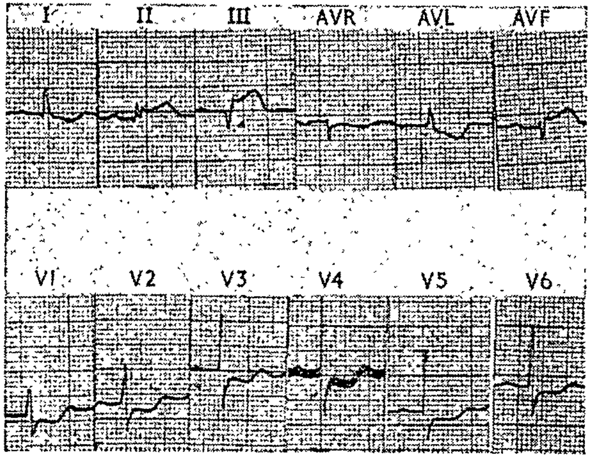

Fig. 4.—Case 4 (30th week of 2nd pregnancy). Sinus rhythm. P–R interval 0.22 second. Abnormal S–T segment and T-wave displacement upwards, due to injury current in leads II, III, and AVF, and downwards in leads I, AVL, and V1–V6. The tracing is consistent with acute postero-diaphragmatic infarction and anterior-wall ischaemia.

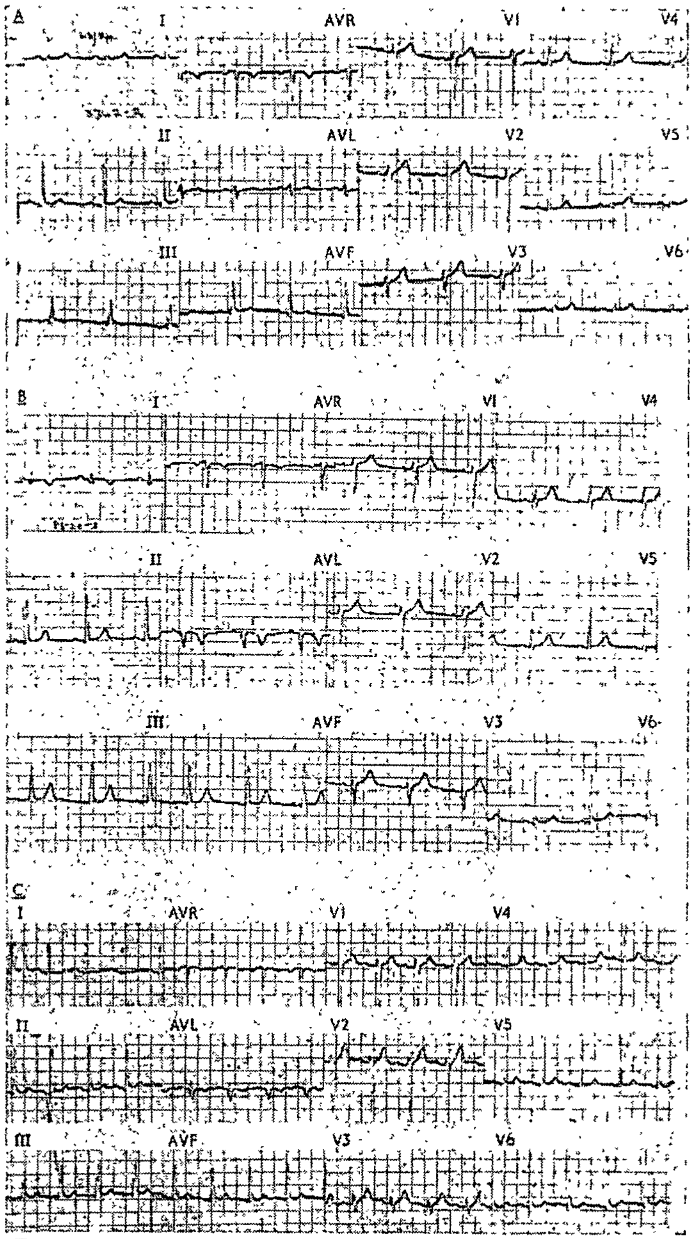

Fig. 5.—Case 5. A (10 months before B). Normal tracing. B (13th week of 22nd pregnancy—10 months after A). Sinus rhythm. Abnormal S–T segment and T-wave displacement with increased polarity of T waves in leads I and AVL. Abnormal Q–S deflection in lead AVL. The tracing is consistent with recent anterolateral infarction. C (4 months after B). In interval following B considerable correction of repolarization has taken place but the tracing still remains abnormal.

developed her episode of coronary occlusion as early as the thirteenth week of gestation and she was the only one in our series in whom the serum cholesterol was significantly raised.

The diagnosis of myocardial infarction during pregnancy presents clinical and electrocardiographic difficulties. Accessory laboratory investigations for myocardial necrosis have to be interpreted with reservations. Upper abdominal pain, flatulence, and even chest discomfort are so common during normal pregnancy that they may mask ischaemic heart pain. The true nature of such symptoms may be obvious only retrospectively when an incidental electrocardiogram is recorded, as in the case reported by Watson *et al.* (1960). Normally the erythrocyte sedimentation rate increases progressively, reflecting changes in plasma proteins. Leucocytosis occurs, and at term the white cell count may be as high as 15,000/cu. mm. (Tysoe and Lowenstein, 1950). There is evidence that normally the serum aspartate aminotransferase activity does not deviate, though it may be elevated in toxaemia of pregnancy (Crisp *et al.*, 1959). Serum lactic dehydrogenase is a much less reliable index of myocardial necrosis, as it may be raised *in normal* pregnancy, and in particular during the puerperium. According to Smith and Gatenby (1958) this enzyme is elevated in 18% of antepartum patients and in 100% of postpartum patients.

Objective evidence of myocardial infarction, therefore, will depend on electrocardiographic analysis, and account must be taken of the electrocardiographic changes which may occur during pregnancy when the heart is not primarily involved. In the later months the mean QRS axis may rotate leftwards owing to elevation of the diaphragm (Hollander and Crawford, 1943) and a deep Q deflection may appear in lead III (Thomson *et al.*, 1938). Acute pulmonary embolism may produce abnormal Q deflections, especially in lead III and S-T segment and T-wave changes, which may mimic postero-diaphragmatic infarction. In addition, electrolyte imbalance may alter the voltage and polarity of the T waves. Intrinsic myocardial disease other than infarction, such as myocarditis of pregnancy, may produce electrocardiographic changes indistinguishable from infarction. In short, electrocardiographic abnormalities must be correlated with all the clinical data. The subsequent history of our patients supports the view that the grossly abnormal tracings were in fact due to myocardial infarction.

Summary

Acute myocardial infarction is rare in pregnancy. The cases of five elderly multigravidae suffering from this condition are described. The diagnosis during pregnancy may present clinical and electrocardiographic difficulties. The increased load on the heart and changes in the blood lipids may predispose to acute infarction in late pregnancy in women with pre-existing coronary atherosclerosis.

Our thanks are due to our obstetric colleagues of the Jubilee and Gardner Robb Maternity Hospitals, who kindly referred their patients to us for cardiac assessment.

Oil Mist Hazard and Piped Air Supplies

JOHN A. BUSHMAN,* L.M.S.S.A.; PETER A. CLARK,† M.B., M.C.PATH.

Brit. med. J., 1967, **3**, 588–590

During recent years there has been a considerable increase in the use of piped air supplies in hospitals. In intensive therapy units this air may often be used to ventilate patients directly.

A system of this type was installed in the intensive therapy unit at Barnet General Hospital and has been in regular use from January 1965. The supply was provided by duplicate oil-lubricated Lacey–Hulbert compressors, each capable of delivering 5½ cu. ft. (0.156 cu. m.) of air per minute at 100 lb./sq. in. (7 kg./sq. cm.). These compressors were installed in the cellar below the intensive therapy unit, together with a reservoir of 33 cu. ft. (0.935 cu. m.) capacity. A Hymatic "rectifier" was installed to remove water. The compressed air was delivered by copper piping to five bedside outlets each equipped with B.O.C. flowmeters.

Some months later it was noticed that some of the flowmeter bobbins were inclined to stick. One of the flowmeters appeared to be slightly oily, and the possibility of oil mist contamination was considered. When the valve of this flowmeter was completely opened to a point far beyond its normal setting, a ripple of oil could be seen on the side of the meter tube (Fig. 1). This excessive air flow had presumably dislodged a quantity of oil trapped below the valve.

An investigation to find the extent of this oil contamination was started. In view of the extremely small quantities of oil mist likely to be present in the air, it was decided to use a fluorimetric technique for oil estimation (Parker and Barnes, 1960).

Methods

Oil mist was collected by passing a known volume of air through filter paper held in a special device consisting of two recessed flanges fitted with hose connexions between which pairs of filter paper discs were held by washers and a spacer. The filter papers used in this work were Whatman paper No. 41, which will cope with low-pressure flows of at least 10 litres per minute. Owing to the rather open nature of the paper, two discs were used in each flange. The papers were

prepared by washing twice with spectroscopic quality cyclohexane (Spectrosol grade—Hopkins & Williams Limited).

The collection device was attached by plastic tubing to the outlet of a flowmeter previously cleaned by washing with cyclohexane. The compressed air was allowed to flow at a known rate for varying periods of time, depending on the amount of oil expected to be present. The collection periods varied from one hour after starting the compressor, following emptying the reservoir, to five days after the fitting of the filter system for the removal of oil mist.

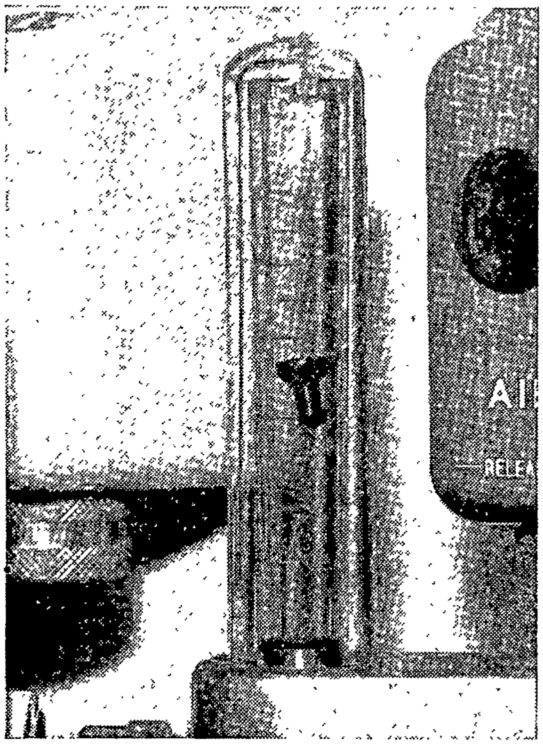

FIG. 1.—Air flowmeter showing ripple of oil when valve fully opened.

After the collection period the central areas of the filter papers which had been in contact with the air channel of the collecting device were cut out and shaken with cyclohexane to extract any trapped oil. The fluorescence of the resulting extracts was read in a Baird-Atomic Fluorescence Spectrophotometer, model SF.1. Under the conditions used it was found that the fluorescence of Shell Talpa 40 oil used in the compressors was maximal at a wavelength of 350 mμ using excitation at 300 mμ (Fig. 2).

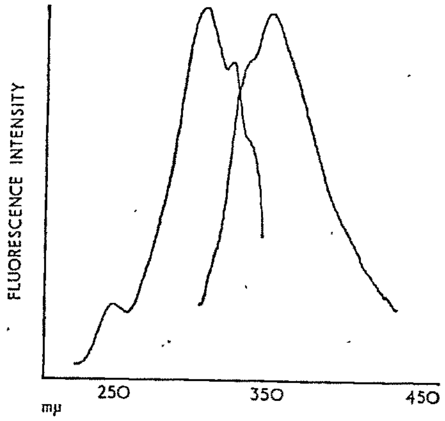

FIG 2.—Excitation (*left-hand curve*) and fluorescence (*right-hand curve*) spectra of crankcase oil.

As it was thought possible that the wick-feed lubrication system concentrated oil in the compressor cylinders after a period of rest, an oil collection was made from air in the reservoir after a 24-hour period during which the compressors had not been run. The reservoir was then emptied and a second sample taken immediately after the compressors had refilled the reservoir.

When the possibility of oil contamination had been confirmed, the British Oxygen Company (who had installed the system) were informed, and they carried out considerable work on the system. This involved the complete cleaning of all equipment, copper piping being replaced wherever easily accessible. The compressors were serviced and arrangements made to drain the excess oil from the sumps at daily intervals. In addition Vokes SPL 10 filters were fitted into the system at points where the air lines entered the intensive therapy unit.

Results

All estimations were made with an air flow of 10 litres per minute. Under the ordinary working conditions of the unit the average amount of oil leaving each flowmeter was 18 μg. per hour. Under the same conditions the amount of oil trapped in the flowmeter was 230 μg. per hour.

After the compressors had been switched off for 24 hours only 6 μg. of oil per hour could be detected in the air leaving a flowmeter attached to the reservoir. After emptying and refilling the reservoir the oil level rose to 70 μg. per hour. After fitting the Vokes SPL 10 filter system, no oil could be detected even in collections lasting 120 hours. After six months' use of the filters no oil could be detected in a 120-hour collection.

Discussion

It seems probable that oil mist contamination of piped air supplies may be a real problem. There appears to have been relatively little work on the problem of oil contamination, though Gerarde (1962) and Cushing and Miller (1965) indicate that chemical pneumonitis may well occur. Although our work has not included any specific estimation of oil particle size, it seems likely, from the relatively small amounts of oil being found, that particle size must be very small.

The provision of oil-free air can be made in two ways—by prevention of oil entering the air at the compressor or by removal of oil found in the compressed air. It is possible to provide oil-free air direct from certain types of compressor, but these are either very expensive or of limited capacity. Compressed air can, of course, be provided from a battery of commercially supplied cylinders, this air having been compressed by a water-lubricated pump and therefore free from oil. However, this is a most expensive method and the cost would be prohibitive in a unit such as ours, where several patients may be ventilated for periods of weeks or even months.

The technology of oil-lubricated pumps is well understood. They are very reliable, relatively cheap, and readily available. Once the use of oil-lubricated pumps is accepted, the problem becomes one of removing the oil mist, either by filtration or by other means.

To be acceptable, a filter, in addition to efficiently removing the oil, must cause a relatively small pressure drop, be able to operate at a flow rate well in excess of the maximum demand, and be safe at the working pressure of the system. From a practical point of view, it is also essential that the filters should be arranged in such a way that they may be changed while the system is in operation. To this end the British Oxygen Company have fitted a system using Vokes SPL 10 filters equipped with replaceable cartridges No. C.74247. Two of these filters are arranged in parallel, so that the air supply can be maintained while one of the filters is being removed for inspection. These filters deal with oil particles. Oil vapour can be removed by techniques based on absorption, but the cost and maintenance of apparatus of this type make their use impracticable.

During the course of several months, usage of this system has proved satisfactory, and we regard this as an acceptable technique for the removal of oil contamination. Though the filters do not appear to be passing detectable oil after several months' use, it seems reasonable to change the filter elements, costing about 30s. each, at quarterly intervals.

Summary

Patients in an intensive therapy unit were being directly ventilated with air from a piped system. It was suspected that this air could be contaminated by oil mist from the compressors used in the system.

By passing the compressed air through a collection device, it was possible to extract oil in microgram quantities, which were subsequently estimated by spectrofluorimetry. Oil contamination was studied under various working conditions.

Because of the implication of oil mist contamination, successful modifications were made to the air-supply system. Even when collections have been made for several days, oil contamination is now below the level of detection.

We would like to acknowledge the co-operation of the British Oxygen Company, and in particular Messrs. J. Cartwright and V. Owen, who have shown the greatest interest in this problem.

Bronchial Carcinoma with Hypercalcaemia Simulating Cerebral Metastases

N. J. STRICKLAND,[*] M.A., M.B., B.CHIR.; A. M. BOLD,[†] M.A., B.M., B.CH.; W. E. MEDD,[‡] M.D., M.R.C.P.

Brit. med. J., 1967, 3, 590–592

The occurrence of hypercalcaemia in patients with a neoplasm without bony metastases has been recognized for some years. The symptoms and signs of hypercalcaemia may dominate the clinical picture. In particular, vomiting and mental disturbance might lead to an erroneous diagnosis of cerebral metastases, so that surgical removal of the primary growth is not attempted and a hopeless prognosis is given. Correct diagnosis with excision of the neoplasm may lead to symptomatic and biochemical recovery. The following case illustrates these points.

Case Report

A woman aged 54 complained of nausea and vomiting since an attack of diarrhoea three weeks previously. The vomiting occurred regardless of eating, and there was no abdominal pain or indigestion. She had also noticed lethargy, weakness, impairment of concentration and reasoning, and had had hiccups on and off for a month. She had always been constipated, and had passed urine once nightly for six months. She had lost 1 stone (6.4 kg.) in weight. She had had a cough since an episode of influenza eight months previously, and had smoked 30 cigarettes a day until 18 months before admission.

On examination there was moderately severe weakness of hip flexion and knee extension, and slight weakness of knee flexion on both sides. Her mental concentration was impaired. She sometimes used the wrong words, and her performance at "serial sevens" was impaired.

Investigations

The serum calcium and phosphorus results are given in the Table. Hb 13.9 g./100 ml.; W.B.C. 9,200/cu. mm.; E.S.R. 70 mm. in one hour; blood urea 28 mg./100 ml. Plasma electrolytes: sodium 144 mEq/l.; potassium 3.6 mEq/l.; chloride 94 mEq/l.; bicarbonate 34 mEq/l. Liver-function tests: total bilirubin less than 0.5 mg./100 ml.; thymol turbidity 2.5 units; cholesterol 260 mg./100 ml.; alkaline phosphatase 11 K.A. units; S.G.O.T. 15 sigma units; S.G.P.T. 10 sigma units; serum albumin 4.9 g./100 ml.; serum globulin 2.9 g./100 ml.; electrophoresis: increase in α_1- and α_2-globulin and mucoprotein.

Results of Serum Calcium and Phosphorus Determinations Before and After Operation

Creatinine clearance 84 ml./min.; urine calcium 136 mg./24 hours; renal phosphate excretion index, +0.09 (normal 0±0.09—Nordin and Fraser, 1960).

The sputum showed numerous malignant cells, probably squamous in origin. Chest *x*-ray film (see Figure) showed a large tumour in the right upper lobe obstructing the upper-lobe bronchus with some deflation of the upper lobe. No lesion in the oesophagus, stomach, or duodenum was found on barium-meal examination. A radiological skeletal survey showed no bony metastases. *X*-ray examination of hands, feet, and teeth revealed moderate generalized decrease in bone density but no cortical erosions in the phalanges. There was some irregularity of the lateral parts of the lower radii and lower part of the humeri resembling hypertrophic pulmonary osteoarthropathy. The periodontal membrane in the lower jaw was slightly ill-defined. Bronchoscopy (Miss M. C. Waterfall) showed pus coming from the right upper lobe.

X-ray film of chest showing tumour in right upper lobe.

Lumbar puncture produced clear fluid at a pressure of 90 mm. H_2O. There were 283 R.B.C.s/cu. mm., 60 mg. of protein per 100 ml., with excess of globulin, and 100 mg. of sugar per 100 ml. An electroencephalogram (E.E.G.) (Dr. D. Williams, Atkinson Morley's Hospital) was reported as showing very abnormal records, with recurrent phases of 1 c/s rhythms occurring equally throughout both hemispheres (possibly the result of high pressure), with evidence of extensive local damage also in the right temporal lobe, compatible with a tumour.

An electromyogram (E.M.G.) was reported by Dr. R. G. Willison (National Hospital, Queen Square) as follows: "Right quadriceps and tibialis anterior were sampled with a concentric needle electrode. There was no fibrillation, and the motor unit potentials on voluntary effort did not appear to be abnormal. On maximum voluntary effort a full pattern was seen, but there was striking fatigue after a few seconds and the pattern became rapidly reduced. Surface electrodes were placed over the left extensor digiti brevis. On stimulation of the anterior tibial nerve the muscle action potential measured over 5 mV with normal latency. In conclusion the only abnormality is the rapid fatigue during voluntary effort."

Course and Treatment

Prednisone 20 mg. twice daily was given for only two days, when it was decided to remove the tumour. In the two weeks before operation her vomiting improved, though it did not stop. On 19 September 1964 she had a right upper lobectomy (Miss M. C. Waterfall). The specimen was reported on by Dr. M. E. A. Powell as follows: "Virtually the whole of the upper lobe was distorted by solid tumour, and histology showed that all but a small part of the base of the upper lobe was replaced by a nodular rounded growth. Microscopy showed an anaplastic carcinoma with a suggestion of a squamous pattern."

Her serum calcium returned to normal levels within 24 hours of the operation (see Table). Her mental state gradually became normal. The power in her legs improved, and three weeks after operation she had only slight weakness of left hip flexion and left knee flexion, all other movements being normal. Two months after operation there were no abnormal neurological signs. Nine months after operation she was symptom-free and there was no clinical or radiological evidence of recurrence of the neoplasm. She was back at her skilled clerical duties and was again solving a daily crossword which she had had to give up preoperatively. She was still symptom-free 18 months after operation.

A postoperative E.E.G. on 18 January 1965 (Dr. F. G. Campbell, Guy's Hospital) was reported on as follows: "Symmetrical 10 c/s alpha rhythm posteriorly, much fast activity which was widespread, and occasional runs of 8 c/s rhythm in the temporal areas. At rest, and more so during overbreathing, small sharp waves were seen in the right frontotemporal channels, and less often independently on the left, where low-voltage irregular theta waves also occurred. Thus the original gross abnormality of the E.E.G. had cleared up, but the second record showed a different type of abnormality suggestive of possible epileptogenic discharges in both temporal lobes." A postoperative E.M.G. on 22 July (Dr. R. G. Willison) was reported on as follows: "Right tibialis anterior and quadriceps were sampled with a concentric needle electrode. The appearances of motor units and the pattern on volition were normal. In particular, the pattern was well sustained, in marked contrast to the appearances preoperatively."

Discussion

The common clinical features of hypercalcaemia are mental disturbance, weakness, anorexia, and vomiting. Additional features may be too nonspecific to arouse much attention—for example, vague abdominal pains, constipation, mild polyuria, loss of weight, lethargy, drowsiness, or cardiac irregularities. Renal calculi, uraemia, and calcific or band keratitis seem to be uncommon in malignant cases, possibly because of the short duration of the hypercalcaemia. In the present case it seems likely that the mental symptoms, vomiting, and weakness of the legs were caused by the hypercalcaemia, though it is impossible to exclude an effect of the neoplasm on the nervous system mediated in other ways. Certainly the E.M.G. findings were similar to those in a patient with hypercalcaemia due to a parathyroid adenoma who was recently seen at this hospital.

In hypercalcaemia the E.E.G. may show diffuse alterations (Lehrer and Levitt, 1960; Krane and Roth, 1964) or suggest focal damage without presence of cerebral metastases. In the present case the E.E.G. before operation showed evidence of extensive local as well as diffuse damage. The E.E.G. after operation showed clearing of the original gross abnormality with residual, possibly epileptogenic, discharges in both temporal lobes. The E.M.G. before operation indicated rapid fatigue during voluntary effort. The E.M.G. after operation was normal. There is uncertainty about the significance of the changes in E.E.G. and E.M.G., which are described so that they can be compared with the findings in future cases.

Possible Causes

Of the possible causes of hypercalcaemia in this patient, vitamin-D overdosage, milk-alkali syndrome, and acute bone atrophy were excluded by the history. Serum electrophoresis and bone x-ray examination produced no evidence of multiple myeloma, though a bone-marrow examination was not made. There was no clinical or radiological evidence of sarcoidosis. The hypercalcaemia was thought to be caused either by the lung carcinoma or by coexisting primary hyperparathyroidism (Dent and Watson, 1964). The biochemical findings may be identical in these conditions, and distinction is often impossible. Estimation of plasma chloride has been claimed to be of help in distinguishing hyperparathyroidism from other causes of hypercalcaemia (Wills and McGowan, 1964). The presence of vomiting, however, as in this patient, might invalidate its usefulness. It was decided first to operate on the lung carcinoma. The fall in serum calcium to normal within 24 hours of the operation, and the persistently normal serum calcium and phosphorus in the next nine months, indicated that the lung carcinoma was the cause of the hypercalcaemia.

Bronchial carcinoma (squamous-cell type) is the commonest neoplasm to cause hypercalcaemia in the absence of bone metastases (Locks, 1962; Krane and Roth, 1964). In a series of 119 cases of carcinoma of the bronchus, Locks (1962) reported that 11% had a moderately raised serum calcium (11.5–13 mg./100 ml.) without symptoms of hypercalcaemia, but 50% of this group had radiologically demonstrable skeletal metastases; 2% had a serum calcium around 16 mg./100 ml., with classical symptoms of hypercalcaemia, and no skeletal metastases; and 9% of those with a normal serum calcium had skeletal metastases. Neoplasms in a wide variety of organs have also been reported to cause hypercalcaemia (Plimpton and Gellhorn, 1956; Watson, 1963; Krane and Roth, 1964).

Biochemical investigation characteristically shows a raised serum calcium, the serum inorganic phosphate tending to be low (Plimpton and Gellhorn, 1956). The proportion of ionized calcium is said to be normal, and there is no increase in the complexed fraction (Walser, 1962; Watson, 1963). Corticosteroids in some cases reduce hypercalcaemia (Lucas, 1960; Locks, 1962), but in others they have little or no effect (Krane and Roth, 1964). This suggests that the two groups have a different pathogenesis.

Possible Mechanisms

Several mechanisms for the hypercalcaemia have been proposed. Of these the production of a vitamin-D-like substance is unlikely. Successful treatment of the causative neoplasm is usually followed by a fall in the serum calcium to normal within four days, which would not be expected with cessation of production of a relatively long-acting substance such as vitamin D (Howard and Thomas, 1963). The second possible mechanism is that the tumour produces a substance, "X," which stimulates the parathyroids (Stone *et al.*, 1961; Krane and Roth, 1964). Supporting evidence is that some tumours are associated with chief cell hyperplasia of the parathyroid glands (Massaro and Owen, 1962; Krane and Roth, 1964), and subtotal parathyroidectomy has caused lowering of the serum calcium (Stone *et al.*, 1961). Evidence against this view is that several authors have reported that the parathyroids are histologically normal, though this does not exclude hyperplasia (Plimpton and Gellhorn, 1956; Massachusetts General Hospital, 1961).

In addition, Goldberg *et al.* (1964) commented that the parathyroids at necropsy of one of their patients weighed much less than normal. The most probable mechanism is that the tumour produces a parathyroid-hormone-like substance as first suggested by Albright and Reifenstein (1948). Direct evidence in favour of this hypothesis has been provided by quantitative complement-fixation tests (Goldberg *et al.*, 1964; Tashjian *et al.*, 1964). These authors reported that extracts of primary and secondary carcinoma causing hypercalcaemia contain an antigen indistinguishable from parathyroid hormone. The concentration of this parathyroid-hormone-like substance has been much lower than that found in the parathyroid, but with large tumours the total amount has been comparable to the total in the parathyroid glands. It is possible, however, that there may be more than one mechanism for the hypercalcaemia in these patients.

In the present case the high serum calcium and low serum inorganic phosphate suggest increased production of a parathyroid-hormone-like substance. In the absence of examination of the parathyroid glands and humoral assay of the tumour removed it is not possible to decide whether the tumour was producing a substance having the activity of parathyroid hormone or a "parathyrotropic" hormone.

The urine calcium in this patient was unusually low (136 mg./day) in relation to a serum calcium of about 16 mg./100 ml. and a creatinine clearance of 84 ml./minute, though the patient's calcium intake may have been on the low side because of anorexia. Parathyroid hormone is thought to increase renal tubular reabsorption of calcium, but this action is normally insufficient to compensate for the increased filtered load of calcium in hypercalcaemia. Indeed, nearly all the reported cases of hypercalcaemia due to malignant disease have a raised urinary calcium (Plimpton and Gellhorn, 1956; Goldberg *et al.*, 1964) though unexplained low excretion of urine calcium has been reported (Massachusetts General Hospital, 1961; Goldberg *et al.*, 1964). Ionized and complexed calcium fractions were not measured in this patient, but the serum proteins were normal, so there is no reason to suspect that the proportion of ionized calcium was abnormal. The occasional finding of an unexpectedly low excretion of urinary calcium in patients with hypercalcaemia due to malignant disease is of interest, as it raises the possibility of another factor affecting urinary calcium excretion.

Summary

A case of hypercalcaemia from carcinoma of the bronchus without bony metastases is described in which some of the symptoms of hypercalcaemia resembled those of cerebral metastases. Removal of the tumour resulted in a rapid return of the serum calcium to normal, with relief of symptoms.

Our thanks are due to Dr. M. J. McArdle for his neurological assessment of the patient before and after operation; to Dr. B. W. Meade and Dr. M. E. A. Powell for advice on the biochemical and morbid anatomical aspects respectively; and to Dr. S. Holesh for advice on the radiology.

Choice of Method for Administration of Oxygen

I. D. GREEN,* M.B., M.R.C.P.

Brit. med. J., 1967, 3, 593–596

The need for carefully controlled continuous oxygen therapy for patients with chronic obstructive airways disease has been amply stated (Campbell, 1960; Hutchison *et al.*, 1964). Further, it has been suggested that patients with cardiogenic shock require as high a concentration of oxygen as possible in the inspired air (MacKenzie *et al.*, 1964). It is surprising, therefore, that, with the exception of the Ventimask, little or no information is provided by the manufacturers of the many devices at present available in regard to the concentrations of oxygen likely to be delivered to the patient. Few data have been published comparing the performance of these various pieces of equipment in an attempt to define which is the most appropriate to use in a given set of circumstances.

Campbell (1960) pointed out the danger of intermittent oxygen therapy and the need for continuous administration, and it is not uncommon for a patient to be treated continuously with oxygen for several days. Clearly, then, the method used should be comfortable for the patient and should interfere with his activities and those of his attendants as little as possible. This aspect of oxygen therapy has been largely ignored by those writing on the subject.

This paper describes the investigation of a number of methods of oxygen administration commonly employed. The aspects that have been particularly examined are: (1) how accurately the concentration of oxygen that each delivers can be predicted; (2) to what extent rebreathing occurs; and (3) how comfortable and convenient the methods are.

Recommendations are made about which device is likely to be the most appropriate one for the condition being treated. The methods that have been examined in detail are: (1) the Addis nasal cannula made by Portex Ltd. (Addis, 1963); (2) the Bardic nasal cannula made by Bard Inc.; (3) the Edinburgh mask made by British Oxygen Co. (Flenley *et al.*, 1963); (4) the Ventimask made by Oxygenaire Ltd. (Campbell and Gebbie, 1966); (5) the Polymask made by British Oxygen Co.; and (6) the Pneumask made by Oxygenaire Ltd.

Methods

To Determine the Concentration of Oxygen Delivered

No direct measurement could be made of the inspired oxygen concentration (F_IO_2) when the nasal cannulae or the Edinburgh mask were worn. A method of human tomometry was therefore employed. Four normal men aged 28 to 34 acted as subjects. After an initial period of rest of 15 minutes each breathed in succession five mixtures of oxygen in nitrogen. The concentrations of oxygen ranged from 21 to 48%. They breathed each gas for half an hour through a close-fitting oronasal mask. Over the last three minutes of each half-hour blood was withdrawn from an indwelling brachial artery catheter and analysed for its oxygen partial pressure (Pao_2) with a Clark electrode (S.D. ± 1.13 mm. Hg) (Bishop, 1960). The $Paco_2$ was also measured with a Severinghaus electrode and compared with the resting value to ensure that no significant hyperventilation had occurred. A graph was then constructed for each subject relating Pao_2 to the impaired oxygen concentration as a percentage (F_IO_2). The same subjects then each wore a nasal cannula and the Edinburgh mask in turn, and the blood gases were again measured after the same length of time. (It had previously been shown that the two nasal cannulae gave identical results.) It was then possible to read from the subject's calibration curve what his F_IO_2 had been. Three measurements were made at oxygen flows of 1, 2, and 4 l./min. for each of the devices.

The same procedure was carried out with the subjects wearing a 27% Ventimask with oxygen flows of 1, 2, and 4 l./min. As the mask was also assessed by direct measurement this served as a means of checking the accuracy of the blood gas method.

In two subjects wearing the nasal cannulae a comparison of the blood gas values was made during nose-breathing and mouth-breathing.

It was possible to make direct measurements of the F_IO_2 with the three other masks. The same four subjects were used for the Ventimask. Four other normal men aged 23–31 years were used for the polyethylene masks. A respiratory mass spectrometer was used to obtain breath-by-breath measurements of the F_IO_2 and F_ICO_2 at 2, 4, 6, and 8 l./min. of oxygen flow. The probe was inserted into a very short mouthpiece, a hole being cut in the two polyethylene masks for the purpose in such a way that it did not interfere with the mask's action. The nostrils were blocked. Recordings were made for three minutes at the end of half an hour at each level of oxygen flow. The minimum inspired CO_2 concentration was measured from the traces and an estimate of the mean inspired CO_2 was made.

Comfort and Convenience

Six male patients between the ages of 45 and 68 years took part to assess the comfort of the devices. Three suffered from chronic bronchitis and had had previous experience of wearing oxygen masks. At the time of the study they were in a quiescent phase of their disease and were not hypercarbic. The other three patients did not have pulmonary disease and had never worn a mask before.

Each patient wore the six devices for an hour each. The order in which they wore them was devised so that any one particular device was worn immediately after any other on as few occasions as possible. The patients were given at least three hours' rest between masks, and were never asked to assess more than two in one day. At the end of each hour they were given a piece of paper on which there was drawn a line 10 cm. in length. This was marked at one end "No discomfort" and at the other "Intolerable discomfort." They were asked to put a cross on the line at a point which they thought represented the degree of discomfort they had experienced during the preceding hour. The distance in millimetres of this cross from the end marked "No discomfort" was taken as a measure of the degree of discomfort (Gedye *et al.*, 1961). None of the six patients found any difficulty in understanding the method. They were also invited to make comments against or in favour of the device they had just tested.

Blood gas measurements were made in patients wearing some of the devices tested.

---

* Lecturer in Clinical Medicine, Department of Medicine, Queen Elizabeth Hospital, University of Birmingham, Birmingham 15.

Finally, three types of oxygen tents were evaluated; the findings are discussed below.

Results

Inspired Oxygen Concentration.—The calculated F_IO_2 values for the nasal cannulae, the Edinburgh mask, and those of the Ventimask determined by the blood gas method are given in Table I. The mean values for nasal cannulae at 1, 2, and 4 l./min. were 27, 31 and 36% respectively, for the Edinburgh mask 28, 33, and 37%, and for the Ventimask 26, 27, and 28%. By direct measurement the inspired oxygen concentrations provided by the Ventimask at all flows did not alter from 27% by more than ±1% (Table II). The mean values for the Polymask were 36, 52, 70, and 77% at 2, 4, 6, and 8 l./min. flow, and for the Pneumask, 30, 50, 69, and 75%.

TABLE I.—*Inspired O_2 Concentrations of the Three Devices as Estimated From the Blood Gas Measurements of Subjects A, B, C, and D*

Method of Administration	O_2 Flow (l./min.)	Inspired O_2 Concentration				
		A	B	C	D	Means
Nasal cannula	1	27	25	29	27	27

	4	46	49	52	54	50
	6	60	65	70	82	69
	8	61	72	76	84	73

Effect of Mouth-breathing.—In one subject the PaO_2 was 10 mm. Hg higher when he was nose-breathing than when breathing through the mouth wearing a nasal cannula. This corresponded to a difference of 1.4% in his F_IO_2. In the other subject there was no difference.

Rebreathing.—The nasal cannulae could not have caused rebreathing. The Edinburgh mask was most unlikely to have done so, and that with the Ventimask proved to be negligible. The two polyethylene masks, on the other hand, caused a very significant degree of rebreathing. The mean *minimum* F_ICO_2s are given in Table III. The *mean* F_ICO_2s while the subjects were wearing the Pneumask at oxygen flows of over 4 l./min. were as high as 3%.

TABLE III.—*Minimum Inspired O_2 Concentrations in Subjects E, F, G, and H Wearing the Pneumask and Polymask at Various Oxygen Flows*

	Polymask				Pneumask			
O_2 flow (l./min.) ..	2	4	6	8	2	4	6	8
Mean minimum F_ICO_2	1·5	0·8	0·4	0·3	1·3	1·8	1·9	1·9

Comfort

The distances of the patients' marks indicating their discomfiture from the end of the lines are shown as the "degree of discomfort" in Fig. 1, together with the mean values. All the patients clearly preferred the nasal cannulae. The order of preference for the masks was, Edinburgh mask, Polymask, Ventimask, and Pneumask. The mean scores for these masks were not greatly different from each other, however, and it would be wrong to place too much emphasis on this order. The additional remarks made by the patients were interesting. Such comments as "I didn't know I had it on," "Would wear it for any length of time with pleasure," "Very comfortable" were made about the cannulae. Almost without exception the patients made the point that they could get to their face and feed with comfort, and all three bronchitics noticed that they could spit. During the F_IO_2 measurements it had been found necessary to humidify the gas with a Wright nebulizer, otherwise the subjects had a burning feeling in the nostrils at 4 l./min. flow.

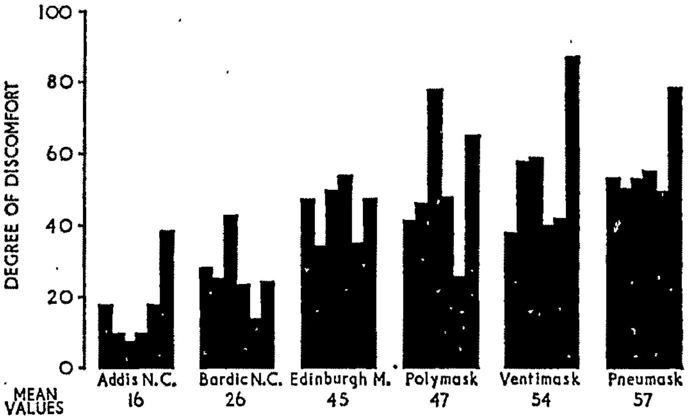

FIG. 1.—Results of six patients' assessment of the comfort of the six devices. Mean values are given—the higher the value the greater the discomfort.

The main objections to the masks were that they all, with the exception of the Ventimask, became hot and sweaty. Most patients noticed discomfort over the bridge of the nose with the Edinburgh mask, the Polymask, and the Ventimask. They all obscured vision to some extent—probably not a serious drawback in a very ill patient. For some the polyethylene masks caused an uncomfortable flow of gas into the eyes. One patient commented that he liked the flow of gas from the Ventimask into his face, but another objected to it. By far the most common objection to the masks was that the patients were unable to get to their face.

Discussion

One striking finding which emerged from the trial was the patients' strong preference for the nasal cannulae. As regards their efficiency as a method, the cannulae proved as reliable as the Edinburgh mask in providing inspired oxygen concentrations between 25 and 39% at flows of 1 to 4 l./min. There was a subject-variation at each flow, this variation being related to the tidal volume. The larger this volume the lower the F_IO_2 owing to greater dilution of the oxygen with inspired air. A patient with chronic obstructive airways will therefore tend to have an F_IO_2 near the upper end of each range given in Table I for the cannulae and Edinburgh mask, and it should be remembered that such a patient wearing either of these devices may have an F_IO_2 of as much as 30% at a flow of only 1 l./min.

In spite of the variation between subjects the nasal cannulae gave reproducible values in the same patient. Fig. 2 shows the results obtained in one patient with chronic hypercapnia whose blood gases were measured before and after being given oxygen for an hour by cannula at 4 l./min. on three successive days.

The Ventimask gave a concentration of oxygen that could be predicted with great accuracy. Both methods of assessment gave similar results, which indicated that the indirect blood gas method was valid. Ventimasks are also available that provide an F_IO_2 of 24, 28, and 35%. Six of each of these have been tested in this unit with the mass spectrometer and have proved equally reliable.

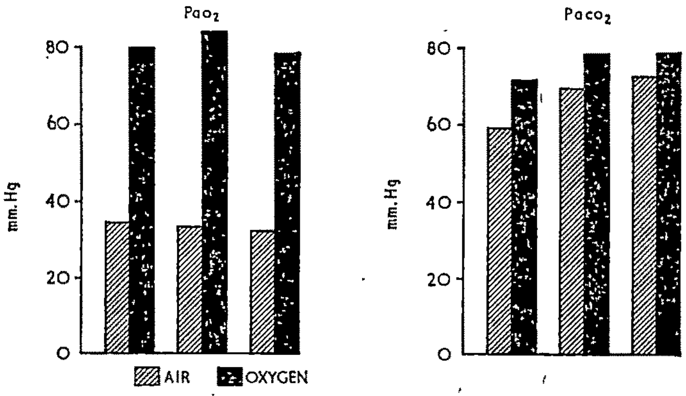

FIG. 2.—PaO_2 and $PaCO_2$ values in one patient measured on three successive days before and after oxygen through a normal cannula at 4 l./min.

The Ventimask's drawback is its lack of comfort. In order to assess whether its ability to control the F_IO_2 accurately outweighs the patient's dislike, consideration has been given to the blood gas results of 38 patients, with chronic obstructive airways disease while in an acute exacerbation, who were treated with oxygen. The measurements were made when the patient was breathing air and after he had received oxygen at 1, 2, or 4 l.min. through a nasal cannula. It can be seen in the oxygen/carbon dioxide diagram in Fig. 3 that if the air-breathing $Paco_2$ was below 60 mm. Hg and the Pao_2 above 45 mm. Hg serious hypercapnia did not develop. With more pronounced blood gas disturbance before oxygen administration a significant rise in $Paco_2$ did sometimes occur. In five patients with a flow of only 1 l./min. $Paco_2$ levels of over 80 mm. Hg were reached. In each case the value on air had been above 70 mm. Hg and the Pao_2 30 mm. Hg or less. Clearly, then, these five patients required less oxygen than could be provided by a cannula to prevent serious hypercapnia and only the 24% Ventimask could have reliably done this. In spite of receiving a lower concentration of oxygen, however, three out of the five patients subsequently required assisted ventilation.

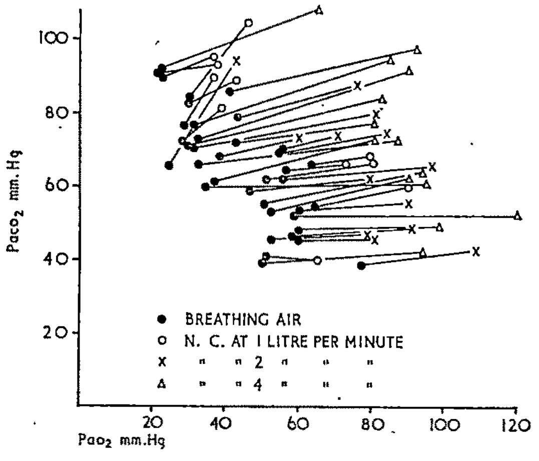

FIG. 3.—Changes in blood gases of 38 patients with obstructive airways disease when breathing oxygen through a nasal cannula at 1, 2, or 4 l./min.

Little information is available on what is the lower level of Pao_2 at which significant harm is done to vital organs. Until detailed studies have been made of regional function in combined anoxia and hypercapnia the safe level can only be guessed at. Hutchison *et al.* (1964) have suggested that the aim should be 50 mm. Hg. In none of the five patients given oxygen by nasal cannula at 1 l./min. did the Pao_2 reach this figure, and the value with the 24% Ventimasks would therefore have been even lower. Nevertheless this mask may be of value in treating those patients with the most severely affected blood gases, especially when assisted ventilation is contraindicated or not available, and perhaps in conjunction with respiratory stimulants. The experience of this department suggests that the facility to deliver 28% or 35% with the same degree of accuracy is not necessary in the management of respiratory failure.

Oxygen Tents

With the exception of their use in very disturbed patients and children, oxygen tents have little value. There are available full-sized tents such as the Oxygenaire MK6 tent and the head tent described by Campbell and Gebbie (1966), that both work on the Venturi principle. These provide constant low concentrations of oxygen with few or no problems of humidity or temperature. However, they do enclose the patient so that he is less accessible and less easy to observe. Patients who need carefully controlled low concentrations of oxygen to prevent hypercapnia will be ill enough to require constant observation and attention, and are better treated with the 24% Ventimask.

At least 6 l./min. of oxygen must be delivered through the Polymask or Pneumask if they are not to be sucked on to the face. In Table II it can be seen that at least 60% oxygen will then be delivered to the patient. Such a high concentration would be likely to induce coma in a patient liable to hypercapnia. At 8 l./min. both masks provide about 80% oxygen. This makes them suitable for treating patients with cardiogenic shock and other conditions requiring a high F_IO_2. Apart from the British Oxygen B.L.B. mask there is no other suitable device commercially available for giving higher concentrations to such patients. Nasal cannulae are unsuitable when a high concentration of oxygen is required, as flows of above 4 l./min. for long periods cause discomfort in the nose. It is therefore unlikely that concentrations in excess of about 40% can be achieved with them. No tents that we have tested have proved satisfactory for giving high concentrations of oxygen. The best that has been achieved by initial flushing and very careful sealing of the tent sides is about 50% inspired oxygen after an hour at 8 l./min.

Care in Prescribing

Any significant degree of rebreathing can be discounted with the cannulae, the Edinburgh mask, and the Ventimask. However, both polyethylene bag masks, in particular the Pneumask, are capable of producing very significant elevations of the F_ICO_2. It should be noted that Table III gives only the minimum values of F_ICO_2, the mean values for the Pneumask being in the region of 3% in the working range. For this reason and because of the high concentrations of oxygen delivered by these two masks they should never be used in the treatment of patients with chronic obstructive airways disease or acute asthma.

A physician must prescribe oxygen with the same care as with any other dangerous drug. The dose should be written on the case sheet in the same way and the nursing staff made aware of its side-effects. The trial has indicated that to provide oxygen to a patient with respiratory failure and hypercapnia—the most difficult situation to prescribe for—the intelligent use of a nasal cannula and a 24% Ventimask, backed up by blood gas measurement or the measurement of the Pco_2 by the rebreathing method, is all that is required, short of assisted ventilation. Furthermore, if such low concentrations as 24% are required, then it is likely that assisted ventilation will be necessary.

In treating patients with other forms of anoxia, when high concentrations of oxygen are needed, the only devices tested that are of value are the Polymask and Pneumask. In such cases the rebreathing they cause is probably not important provided there is no underlying chronic lung disease. There may well be need for the development of a mask that will provide even higher concentrations of oxygen. If such a device becomes available we will still have to prescribe with care because of the dangers of oxygen poisoning and absorption atelectasis.

Summary

A number of devices for delivering oxygen have been evaluated with special regard to what extent the concentration of oxygen they supply is predictable, whether or not they cause rebreathing, and how comfortable and convenient they are. The following conclusions have been drawn:

(1) Oxygen should always be prescribed with care and never left to the whims of untrained staff.

(2) Where there is a likelihood of serious hypercapnia, especially if there is a disturbance of consciousness, P_{CO_2} measurements must be made by one or other of the available methods, and the concentration of oxygen the patient receives should be adjusted according to these measurements.

(3) The vast majority of patients with hypercapnia will tolerate oxygen at 1 litre/min. through a nasal cannula, increasing flows being given if there is no serious rise in Pa_{CO_2} or a lowering of the level of consciousness.

(4) The oxygen must be adequately humidified if given by cannula.

(5) If serious hypercapnia is present—that is, in the region of 70 mm. Hg—a 24% Ventimask may be necessary, but such a patient is likely to need assisted ventilation.

(6) For the delivery of high concentrations of oxygen, but only when hypercapnia is not a problem, either the Polymask or the Pneumask is the most practical method available at present.

It is a pleasure to acknowledge the encouragement and helpful criticism of Professor J. M. Bishop and the technical assistance of Mrs. Anne Hollyhock and Miss Susan Pepper. I would also like to thank Miss Susan Wall for her help in the preparation of the text.

Preliminary Communications

Phagocytosis by Polymorphonuclear Leucocytes from Patients with Renal Failure

Brit. med. J., 1967, 3, 596–599

Acute infections are a common problem in the management of renal failure, though their incidence has not been investigated to the same extent as that of infection in other metabolic disorders such as diabetes mellitus. Experience of infective conditions in renal failure is summed up by Schreiner (1964), who states that "infection is the single leading cause of death even in the well-managed uraemic patient." The infective conditions to which this category of patients is prone are usually those caused by *Staphylococcus pyogenes*, Enterobacteriaceae, and *Pseudomonas* species. These pathogens are resisted principally by the non-specific defences of the host. It appeared worth while, therefore, to examine the phagocytic activity of polymorphonuclear leucocytes from uraemic patients to determine whether renal failure in any way impairs the performance of this means of defence against infection.

Two mechanisms of phagocytosis have been demonstrated in human polymorphs (Brogan, 1966): one is independent of serum and the other is conditional on the presence in the cell environment of serum factors. The present inquiry was designed to examine various aspects of these two mechanisms of phagocytosis in uraemic patients and to compare the findings with those in a group of patients whose renal function was normal.

MATERIALS AND METHODS

Patients.—Twelve uraemic patients were studied, the majority of whom were in chronic renal failure from a variety of causes, details of which are listed in Table I. In parallel, a series of 17 hospital inpatients with normal kidney function were investigated; almost 50% were suffering from myocardial infarction, and the rest were under treatment for a variety of conditions (Table I). All patients of the control group had a normal blood urea, and their polymorphs were examined during the recovery or quiescent phase of their illnesses.

TABLE I.—*Patients: Clinical Data. Levels of Blood Urea Were Those Recorded at Time of Taking Blood for Testing Phagocytic Activity*

Group with Renal Failure			Group with Normal Renal Function	
Case No.	Diagnosis	Blood Urea (mg./100 ml.)	Case No.	Diagnosis

9	" "	405		
10	Chronic urinary retention: bladder diverticulum	395		
11	Staphylococcal septicaemia precipitating acute renal failure	122		
	Acute glomerulonephritis of late onset	440		

Phagocytosis Experiments.—The materials and methods used for the phagocytosis experiments have been described in detail (Brogan, 1964, 1966). Preparations of polymorphs were made by dispersing the buffy layer of heparinized blood in medium 199 (Morgan, Morton, and Parker, 1950) and allowing the white cell suspension to settle on glass coverslips. Red cells and lymphocytes, which do not adhere to glass, were allowed to sediment from the coverslip preparations that were maintained in a vertical plane in medium 199 in a perspex tank. The morphology of the polymorphs was examined by a phase contrast microscope ; the phagocytic activity of the polymorphs was estimated from the proportion of living cells that were seen to contain test particles. Serum-independent phagocytic activity was investigated by determining the percentages of the cell populations that ingested test particles of rice starch in the absence of serum. Serum-dependent phagocytic activity was studied by determining the serum concentration that caused 50% of phagocytosis in the polymorphs under examination. Paraffin wax particles were used as test material because they are ingested by human polymorphs only in the presence of serum components and will therefore test the mechanism of particle ingestion that is entirely dependent on serum factors (Brogan, 1966). The sensitivity of the polymorph preparations to bacterial endotoxin was measured by determining the concentrations of a commercial preparation of lipopolysaccharide from *Salmonella abortus-equi* (Pyrexal) that would cause a 50% depression of phagocytic activity as compared with a control. Rice starch was used as test particle in these experiments, which were carried out in serum-free medium.

Ultrafiltration of Serum.—Ultrafiltrates of serum from individual patients were prepared by using 8/32 Visking tubing.

Complement Titrations.—A series of logarithmic dilutions of the patients' serum were made in 0.75 ml. of Dulbecco solution (Dulbecco and Vogt, 1954) and added to 0.25-ml. aliquots of a 3% suspension of sheep red cells sensitized with rabbit anti-sheep-red-cell serum (Stayne Laboratories Ltd., High Wycombe, Bucks). After incubating the tubes at 37° C. for 30 minutes the red cells were centrifuged at 400 *g*, and the degree of haemolysis in the supernatant was estimated by reading the optical density of a tenfold dilution at 418 mμ on a Unicam S.P. 500 spectrometer in a 1-cm. cuvette, a standard curve being used to calculate the percentage of haemolysis. The concentrations of serum were plotted on the log scale of log-probability paper against the percentages of haemolysis, which were plotted on the probability scale. The concentration of serum causing 50% of haemolysis ($C'H_{50}$) was read directly from the graph.

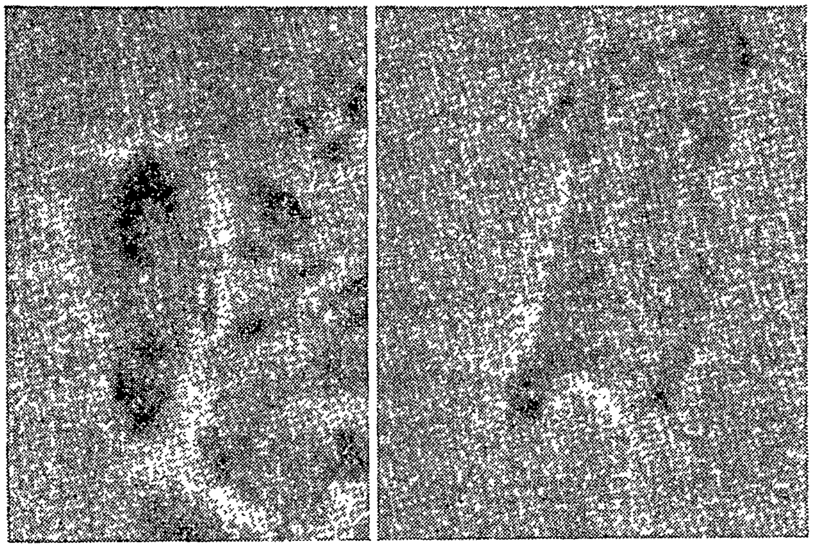

FIG. 1.—Left: Phase contrast photograph of a polymorph from a patient with normal renal function. Right: Phase contrast photograph of a polymorph from a patient with renal failure. (×1,000.)

RESULTS

MORPHOLOGY OF POLYMORPHS FROM URAEMIC PATIENTS

When viewed under phase contrast the morphology of living polymorphs from patients with renal failure was seen to be different from that of cells from patients with normal kidney function. This difference is illustrated in Fig. 1. The cells from uraemic patients appeared to spread on the glass more than those from patients with normal renal function, giving the illusion that the polymorphs from the uraemic patients were the larger of the two. Cytoplasmic granules appeared to be more prominent and vacuoles more common in polymorphs from patients in the renal failure group than in cells from patients with normally functioning kidneys. In addition there was a greater tendency for polymorphs from uraemic patients to form long cytoplasmic processes as compared with cells obtained from the control group of patients.

SERUM-INDEPENDENT PHAGOCYTOSIS

The ability of polymorphs from uraemic patients to ingest rice starch test particles was found to be significantly less ($P<0.005$) than that of polymorphs from patients with normal renal function (Table II). The magnitude of this difference in ability between polymorphs from patients with kidney failure and those from the control group was not large. The results in Table II show that the average phagocytic activity of cells from uraemic patients was almost 90% of that of cells from patients with normal renal function. The variation in the results in cell preparations from individual patients, which was higher in the renal disease group than in the control group, did not appear to be related either to the aetiology of the renal failure or to the level of blood urea at the time of measurement.

TABLE II.—*Phagocytosis of Starch Particles by Polymorphs From a Group of Patients With Renal Failure and From a Group With Normal Renal Function. Tests were Carried Out Either in the Absence of Serum or in Medium Containing Ultrafiltrate of Serum of Individual Patients From Both Groups*

	50% v/v of serum ultrafiltrate from group with normal renal function	78%	67–81%	8

* Difference significant at $P<0{\cdot}005$.

The effect on phagocytosis of adding ultrafiltrates of sera from both groups of patients to the medium was also studied. These experiments were designed to determine whether any low-molecular-weight substances that depressed phagocytosis were present in the sera of uraemic patients. Plasma proteins were therefore removed so that the action of any such substances would not be masked by the phagocytosis-promoting effect of complement (Brogan, 1964). Table II shows that when cells from uraemic patients or from control patients were tested in the presence of 50% of the ultrafiltrate of sera from either group of patients, no significant difference ($P>0.05$) was observed in the percentages of phagocytosing polymorphs. The scatter in results obtained with ultrafiltrates of serum from patients in renal failure was due to a depression in phagocytosis obtained when ultrafiltrates from Cases 1 and 2 were added to the medium ; both these patients were in the terminal phase of their illnesses and died shortly after blood was obtained from them, so it was impossible to repeat the tests. However, depression of phagocytosis was not observed when the ultrafiltrate of serum from another terminally ill patient (Case 9) was added to the medium.

SERUM-DEPENDENT PHAGOCYTOSIS

With the use of paraffin wax test particles normal dose-response curves were obtained when polymorphs from uraemic patients were employed to determine the concentration of serum that caused phagocytosis in 50% of the cells under test (PC_{50}) (Brogan, 1964). It thus appeared that the serum-dependent mechanism of phagocytosis in polymorphs from uraemic patients was unimpaired. In consequence, the complement levels of sera from uraemic patients were determined and compared with those of sera from patients with normal renal function. The results showed that the complement titres of the uraemic group of patients were not significantly lower ($P>0.05$) than those of patients not in renal failure (Table III). Thus the sera of uraemic patients were as capable of promoting phagocytosis in polymorphs as were sera from patients with normally functioning kidneys. The addition of the ultrafiltrates of sera from uraemic patients to a final concentration of 1 : 10 caused no significant depression in the complement titre of sera from either group of patients.

TABLE III.—*Complement Titres of Sera From a Group of Patients With Renal Failure Compared With Those of a Group With Normal Renal Function. FIG. 2.—Titration of effect of bacterial lipopolysaccharide on polymorph preparations. Concentration of endotoxin, in mμg./ml. (10^{-9} g./ml.), was plotted on a log scale against phagocytosing polymorphs, expressed as percentages of normal phagocytosis in the absence of serum, which were plotted on a probability scale ; rice starch was used as test particle. The concentration that depressed phagocytosis by 50% was read directly from the graph. ○——○——○ Polymorphs from a patient with normal renal function. ●——●——● Polymorphs from a patient with renal failure.

SENSITIVITY TO BACTERIAL ENDOTOXIN

As it had been noted that polymorphs of uraemic patients were different in morphology from those of patients with normal renal function (Fig. 1), the sensitivity of cells from both groups of patients to bacterial endotoxin was determined. These estimations were carried out by plotting the concentrations of lipopolysaccharide on the log scale of log probability paper against phagocytosing polymorphs, expressed as percentages of normal phagocytosis, which were plotted on the probability scale (Fig. 2). Rice starch was used as test particle, and Table IV summarizes the results.

TABLE IV.—*Action of Bacterial Endotoxin on Polymorph Preparations From Uraemic Patients and on Preparations Made From Patients With Normal Renal Function. Effect of Lipopolysaccharide is Expressed as Concentration of Endotoxin Required to Cause a 50% Reduction in Ability of Individual Cell Populations to Ingest Starch Particles*

3	2·6	6	10·0
4	1·9	7	12·5
7	1·9	8	9·5
8	4·4	9	8·2
9	2·8	10	8·0
10	3·8	13	9·5
11	1·7	14	8·5

An average concentration of endotoxin of $2.9 \pm 1.1 \times 10^{-9}$ g./ml. was required to depress phagocytosis of polymorphs from uraemic patients by 50% as compared with an average of $9.7 \pm 1.5 \times 10^{-9}$ g./ml. required to produce a similar depression in cells from the control patients. This difference between the effect of bacterial endotoxin on polymorphs from uraemic patients and on cells from patients with normal renal function is highly significant ($P<0.001$). The extent of the difference in the effect of endotoxin is a measure of the far greater sensitivity of polymorphs from uraemic patients to a toxic bacterial product as compared with that of cells from patients with normal kidney function.

DISCUSSION

When the phagocytic activity of polymorphs is under examination in a particular disease the existence of two mechanisms of particle ingestion that are complementary to one another (Brogan, 1966) demands that each is examined in turn lest any effect on one mechanism is masked by the operation of the other. A comparison was made of some aspects of these two mechanisms of phagocytosis in polymorphs from uraemic patients and in polymorphs from hospital inpatients suffering from various illnesses but with normal renal function. The patients with normally functioning kidneys provided a control group that probably avoided bias due to illness alone. Serum-independent phagocytic activity was found to be depressed in polymorphs from uraemic patients as compared with that in cells from the control group, though serum-dependent phagocytosis was not thus lowered. These findings prompted an examination of the cell environment in uraemia for substances that might interfere with phagocytosis, because the extent of this depression in the serum-independent mechanism of phagocytosis was not great. To achieve this, serum proteins were removed by ultrafiltration so that the effect of such substances could be studied in the absence of complement. Ultrafiltration was used for this purpose in preference to the usual procedures for inactivating complement, such as heating at 56° C., because these were thought to be non-physiological.

With the exception of two preparations obtained from patients in the terminal phase of their illnesses, ultrafiltrates of sera from uraemic patients caused no detectable suppression of phagocytosis when polymorphs from either group of patients were tested. Likewise, ultrafiltrates of sera from the uraemic patients did not lower the complement titre of serum.

These results differ from those of Balch (1955), who showed that phagocytosis of staphylococci by polymorphs was not depressed in uraemia of acute onset. Balch, however, tested polymorphs in whole blood so that serum-independent and serum-dependent phagocytosis were not examined separately; depression in serum-independent phagocytic activity therefore could have been missed. Salisbury and Pomeranz (1963) have postulated that toxicity in uraemia is associated with anions which Kramer, Seligson, Baltrush, and Seligson (1965) have identified as aromatic acids. The ultrafiltrates of sera from the uraemic patients in the present investigation probably contained these substances, but little overall effect on serum-independent phagocytosis was produced by their presence; nor had they any effect on the phagocytosis-promoting ability of serum.

It was of interest that the complement levels of sera from uraemic patients were not significantly different from those of patients with normal kidney function. This indicates that the non-specific phagocytosis-promoting activity of serum is not depressed in uraemia. This activity depends on a combination of either the C′1 or the C′2 with the C′4 component of complement (Brogan, 1966), and the complement level of serum is a function of the component in least concentration (Hegedüs and Greiner, 1938). Low-complement levels have been reported in renal disease, particularly in acute glomerulonephritis (Ellis and Walton, 1957), but it would appear that though immunological responses are lowered in uraemia (Wilson, Kirkpatrick, and Talmage, 1965), renal failure as such does not affect the complement level of serum.

The most significant finding of this investigation was the increased sensitivity of polymorphs from uraemic patients to bacterial endotoxin. A 50% depression in phagocytosis was produced in polymorphs from uraemic patients by an average of less than one-third of the concentration of lipopolysaccharide that was required to cause this depression of phagocytosis in cell populations from patients with normal renal function. It is likely that endotoxin stimulates polymorph lysosomes (Brogan, 1966), which are thought by some to be responsible for the self-destruction of cells (de Duve, 1959). It would seem, therefore, that polymorph lysosomes in uraemia are more susceptible to stimulation than normal. This difference is reflected in the difference between the morphology of the cells from patients with and without uraemia; the cytoplasmic granules particularly tend to be more prominent in the cells from uraemic patients than those of the cells from patients whose renal function is unimpaired.

If sensitivity to endotoxin is regarded as a model that indicates how cells respond to toxic bacterial substances in the environment, then polymorphs in uraemia are more susceptible than normal to damage by such substances. The cause of this apparent increase in fragility of polymorphs from uraemic patients is a matter for conjecture. Hypersegmentation has been noted in polymorphs in blood films from uraemic patients (Jensson, 1958), and this could indicate that polymorphs are on the average older in uraemia than in the presence of normal renal function. Whatever the explanation for the apparently increased fragility of polymorphs in uraemia, it may account for the greater than average susceptibility to acute infection in this condition.

SUMMARY

Serum-independent phagocytosis was found to be depressed slightly in polymorphs from uraemic patients, but neither serum-dependent phagocytosis nor the capacity of uraemic serum to promote phagocytosis, as assessed by complement content, was affected. No difference in effect on phagocytosis was found between ultrafiltrates of serum from uraemic patients and from patients not in renal failure. Susceptibility to endotoxin was greater in polymorphs from uraemic patients than in cells from control patients. This difference in sensitivity to a toxic bacterial product may account for the greater than average susceptibility to acute infection in uraemia.

I thank those physicians and surgeons of the Royal Infirmary, Cardiff, who have allowed me access to their patients; and Professor Scott Thomson, Dr. A. W. Asscher, and Dr. M. Sussman for their helpful advice throughout this investigation.

Medical Memoranda

Subcutaneous Atrophy after Local Corticosteroid Injection

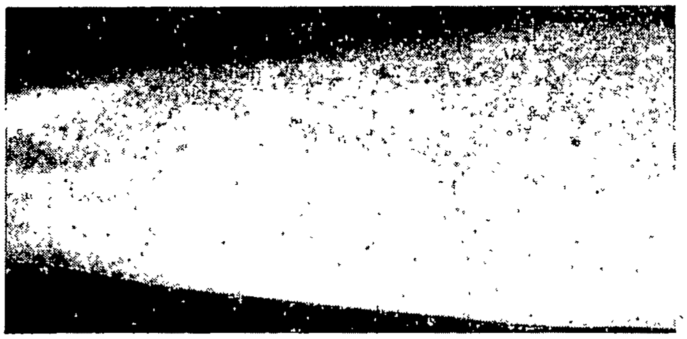
Brit. med. J., 1967, **3**, 600

Atrophy of the skin and subcutaneous tissue at the site of locally applied or injected insoluble corticosteroid preparations was first reported in rats by Baker and Whitaker (1948) and in man by Goldman *et al.* (1953). Since then several further reports of this local complication of corticosteroid therapy have appeared (Goldman, 1955, 1962; Fisherman *et al.*, 1962; Epstein *et al.*, 1963; Meara, 1964; Grice, 1966). All these reports, however, are of patients in whom corticosteroid injections were given for skin diseases or asthma; no reports of this complication occurring in patients treated for arthritis or soft-tissue lesions of the locomotor systems have been found in the literature.

A case in which this complication developed after a local injection of hydrocortisone tertiary butylacetate is described.

CASE REPORT

A woman aged 39 was first seen in June 1965, when she complained of having had pain in the right arm for nine months. Examination showed that she had a right de Quervain's tenosynovitis, and a depressed area of skin about 2 by 1 in. (5 by 2.5 cm.) was noted on the flexor surface of the forearm 4½ in. (11.4 cm.) above the wrist. The overlying skin was of normal colour and consistency and not bound down to the deep tissues. Three small, round, yellow subcutaneous deposits were seen. Clinically the condition appeared to be a small localized area of fat necrosis (see Photograph).



Flexor aspect of forearm, showing depressed area of skin.

The patient had received local corticosteroid injections at another hospital, and subsequent inquiry revealed that when she had been seen eight months previously a diagnosis of de Quervain's tenosynovitis had also been made and treated with two injections of 40 mg. of Depo-Medrone (methylprednisolone acetate) into the tendon sheath of the extensor pollicis longus. There was partial relief of her symptoms, but early in 1965 she complained of pain and numbness along the radial border of the middle third of the forearm, and on 16 March an injection of hydrocortisone acetate was given into this painful area.

Between June 1965 and May 1966 no change in the atrophic area was observed.

On 21 May 1966, because of persistent symptoms, exploration of the right radial nerve and the abductor and extensor pollicis longus tendons was carried out and an extensor tendon release performed by Mr. J. C. R. Madgwick. The patient disliked the appearance of the atrophic area, which was excised at the same time.

Histological examination of this area showed fat necrosis in the subcutaneous tissues and the epidermis was considerably thinned.

DISCUSSION

Animal experiments (Baker and Whitaker, 1948; Castor and Baker, 1950) first showed that local corticosteroids produce thinning of the skin with decrease in the size of sebaceous glands and cessation of hair growth. Later workers showed that very similar changes occur in man.

Goldman *et al.* (1953) reported that deposits of insoluble corticosteroid crystals persist at the site of injection for months and that adjacent skin becomes depressed and atrophic; long-term studies (Goldman, 1955, 1962) confirmed the persistence of the crystals for as long as three years after injection. After their eventual disappearance the skin slowly returned to normal. McKenzie (1962) suggested that these atrophic changes were largely due to ischaemia, as the application of corticosteroids to healthy human skin produced intense vasoconstriction. Schetman *et al.* (1963) studied the effect of local injections of triamcinolone acetate into normal volunteers; they found that long-standing local atrophy was common after intradermal injections and sometimes occurred after subcutaneous injections.

It is suggested that in the case described above the atrophy followed the injection of hydrocortisone into the forearm.

Though local atrophy cannot be regarded as a serious complication of corticosteroid therapy, it is unsightly and may persist for several years. It is suggested that when local injections of insoluble corticosteroids are necessary, deep injections of more dilute suspensions of the corticosteroid, as suggested by Goldman (1962), will lessen the chance of this complication developing.

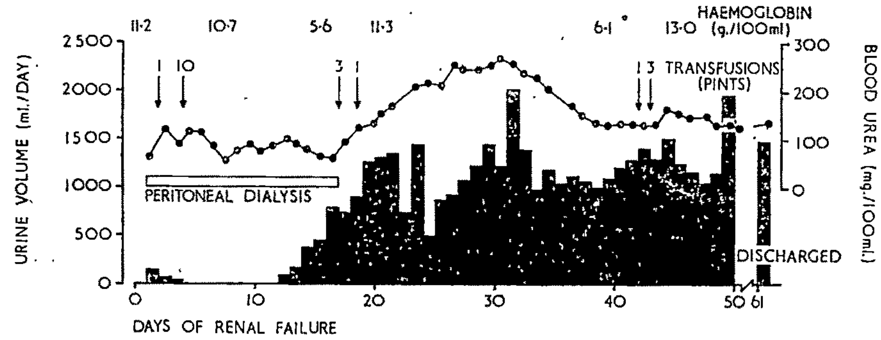
Suicidal Chlorate Poisoning Treated with Peritoneal Dialysis

Brit. med. J., 1967, 3, 601–602

Recovery from chlorate poisoning is rare, and only one case in which dialysis was used has been recorded (Klendshoj *et al.*, 1962). We report here the successful management of a woman who took 40 g. of sodium chlorate in a suicide attempt.

CASE REPORT

The patient, a married woman aged 35, had no history suggestive of renal disease but had a long history of depression. In 1954 and in October 1964 she had been treated for drug overdoses, and in October 1965 for attempted suicide by cutting her wrists. She remained under treatment for three months and was then thought to be well enough to go home. She continued to attend as an outpatient for electric convulsion, which was given at 9 a.m. on 20 December 1965. She walked home alone and took two tablespoonfuls (about 40 g.) of sodium chlorate bought as a weed-killer. She was admitted to Joyce Green Hospital under Dr. P. C. Farrant at 11.15 a.m. Her condition was good, but she began to vomit after arrival. She looked cyanosed and her plasma showed methaemoglobin. She was given methylene blue and vitamin C, and 3 pints (1,700 ml.) of blood were infused and 2 pints (1,140 ml.) removed. She vomited persistently, but by the evening her plasma potassium had risen to 5.4 mEq/l. and her blood urea to 60 mg./100 ml. During the first 18 hours she passed only 90 ml. of urine, and was therefore transferred to Guy's Hospital the next day. Her haemoglobin was 13.5 g./100 ml. and packed cell volume 46%.



The clinical course of the patient.

On arrival during the afternoon of 21 December her condition had deteriorated. She was a khaki colour, with slate-coloured lips and peripheral cyanosis. There were old scars and recent scratches on her wrists and neck. Her pulse was 88/min., blood pressure 120/90 mm. Hg, and respiration rate 22/min. There were no other physical signs. Blood was immediately taken, and had an extraordinary appearance; the plasma was dark opaque muddy brown and the red cells appeared black and shiny like coal dust. Her blood haemoglobin was 10.7 g./100 ml., and spectroscopy showed free haemoglobin, oxyhaemoglobin, methaemoglobin, and methaemalbumin in the plasma. The oxygen saturation was 82% and standard bicarbonate 26 mEq/l. A blood count showed 4% reticulocytes, a white cell count of 52,800/cu. mm., and a platelet count of only 40,000/cu. mm. Though she was anuric, her blood urea was still 60 mg./100 ml.

It was thought that any blood transfused would immediately been oxidized and haemolysed, as her own blood had been, so it was decided to perform a peritoneal dialysis to remove the chlorate before transfusing. An intensive dialysis was begun, being continued (Cameron, 1966) for 24 hours before a 10-pint (5.7-litre) exchange transfusion was started. Throughout these procedures she remained in generally good condition but completely anuric. Her mood seemed normal and she no longer complained of depression. Her subsequent progress is summarized in the Figure.

Her plasma rapidly became free of pigments and was completely clear after six days. Her course was complicated by a number of infections, summarized in the Table. Throughout the whole period of the illness, however, her white blood count remained about 20,000 to 50,000/cu. mm., with a marked left shift even in the absence of serious infection, and continued to be high until day 40.

After a partial diuresis her blood urea remained above 100 mg./100 ml., and after nine weeks in hospital she was discharged with a creatinine clearance of 40 ml./min., urea clearance 9 ml./min., blood urea 118 mg./100 ml., and serum creatinine 4.6 mg./100 ml. When seen at the outpatient department in April she was well, with a blood urea of 46 mg./100 ml., and admission was arranged in May for a full assessment. At that time (five months after admission) there was nothing to find on examination, the blood pressure being normal. Intravenous pyelography showed nothing abnormal, but the creatinine clearance remained low (58 ml./min., serum creatinine 1.3 mg./100 ml.), though the blood urea was normal (32 mg./100 ml.). The urine was sterile and concentration was slightly impaired (1018). Renal biopsy was thought not to be justified at that time.

DISCUSSION

Almost all data on chlorate poisoning concern potassium chlorate rather than sodium chlorate, because of extensive industrial and pharmaceutical use of the potassium salt until about 20 years ago. Witthaus (1911) was able to document 143 cases from the literature then available; Cochrane and Smith (1940) reviewed only a further eight patients, and since publication of their paper 13 cases have been reported (Gordon and Brown, 1947; Oliver *et al.*, 1951; Klendshoj *et al.*, 1962). Ten of these are included in a review of sodium chlorate poisoning by Dérot *et al.* (1948). Apart from these only three case reports (Jacobi, 1879; Stryjzowski, 1931; Klendshoj *et al.*, 1962) refer to sodium chlorate poisoning. The sodium salt may be expected to be even more toxic than the potassium salt, because it contains more chlorate on a weight-for-weight basis (77% as compared with 68%) and is 16 times more soluble in cold water.

* Only on days 18–20 was the dialysate turbid.
† This was the only positive blood culture of many taken.

The fatal dose of chlorate is usually 20–30 g. (Witthaus, 1911). The smallest dose causing the death of an adult is 7.5 g. (Bernstein, 1930) taken in a tooth-paste by a suicidal Army officer ; and the largest dose with survival is 47 g., taken in divided doses over 13 hours (Gesenius, 1882). Previous renal impairment, as in the patient of Cochrane and Smith (1940), would decrease the fatal dose, since 95% of the drug is eliminated in the urine. Few patients survive chlorate poisoning. Blyth (1884) collected 39 cases—28 fatal—and of Witthaus's 143 patients 116 died. The average survival was just over four days, ranging from four hours to 12 days. Renal failure was recorded early. The unfortunate Dr. Fountain took 29.2 g. of potassium chlorate as an experiment to prove its harmlessness in 1858 and died "on the seventh day of nephritis" (Jacobi, 1860).

The symptoms and signs of chlorate poisoning have been well described. After ingestion there is usually a period of one to four hours before vomiting begins, often accompanied by diarrhoea and abdominal pain. Dusky cyanosis and dyspnoea follow, the blood pressure tends to fall, and the heart beat to become irregular. The liver and spleen may be enlarged and tender. The urine is scanty or even absent, is brown or black in colour, and contains casts, red cells, free haemoglobin, and methaemoglobin. The blood is brownish in colour and the plasma contains free haemoglobin and free methaemoglobin. The red count is very low and the white cell count persistently high. Agitation, muscular weakness or twitching, occasionally fits, and a falling blood presure lead to coma and death. Many of these symptoms and signs undoubtedly arise from uraemia and hypoxia. At necropsy the kidneys are brown in colour, hyperaemic, and larger than normal. There are signs of gastro-enteritis, the liver and spleen are enlarged, and the blood is chocolate-coloured.

Apparently chlorate is toxic because it is such a powerful oxidizing agent. It attacks all cells, including liver, kidney, and the circulating red cells (Richardson, 1937). SH groups would be particularly vulnerable. The red cells are largely haemolysed and the released haemoglobin converted to methaemoglobin. The intact red cell has considerable capacity to reduce methaemoglobin to haemoglobin (Jaffé, 1964), but this mechanism presumably cannot operate after haemolysis, and methaemoglobin accumulates. This suggestion is confirmed by Gordon and Brown (1947), who noted that the haemoglobin in the washed red cells of their patient was virtually all true haemoglobin, whereas the free pigment was mostly methaemoglobin. The dangers to the patient are therefore direct tissue toxicity, tissue hypoxia, and haemolysis. The haemolysis could liberate enough free potassium to make the plasma K^+ concentration rise to lethal levels, and this presumably accounts for some of the very rapid deaths. Any patient who goes into immediate renal failure will retain almost all the absorbed dose indefinitely, so that dialysis becomes essential for its removal. The chlorate in the dialysate was not measured, but it is known to be freely dialysable from blood and from tissue in vitro (Witthaus, 1911).

The only other case in which dialysis was performed was that reported in detail by Klendshoj *et al.* (1962) and mentioned by Schreiner (1958) and Doyle (1962). The patient was a 28-year-old Korean physician who took exactly 40 g. of sodium chlorate in mistake for sodium chloride in a laboratory experiment. Haemodialysis was performed on the second day to remove chlorate, and on the eighth and fourteenth days because of renal failure. In addition, an 18-pint (10-l.) exchange transfusion was carried out during the first dialysis. The authors attributed this recovery to prompt exchange transfusion and dialysis. A haemodialysis was begun on one patient (Dérot *et al.*, 1948) but was abandoned after 30 minutes because of clotting problems.

Normally, patients with acute renal failure may be expected to recover renal function completely. The failure of our patient to recover completely presumably reflects some irreversible damage due to direct toxic effect on the renal parenchyma, as well as reversible changes due to the haemoglobinuria. One can only guess whether the peculiar susceptibility of our patient to infection (despite excellent control of blood urea on continuous dialysis) was related to some specific feature of chlorate poisoning.

ADDENDUM.—It has been drawn to our attention that Case 10 of the paper by Pringle and Smith (1964) refers to a 17-year-old youth with renal failure from sodium chlorate poisoning who was treated with peritoneal dialysis for 14 days and who recovered.

Current Practice

FORENSIC MEDICINE AND TOXICOLOGY

Drug Addiction

THOMAS H. BEWLEY,* M.D., F.R.C.P.I., D.P.M.

During the past ten years there has been a change in the pattern of drug addiction in the United Kingdom. Before 1950 there was relatively little, and virtually none among people who had obtained drugs illicitly. Now cannabis, amphetamines, combinations of amphetamines and barbiturates, lysergic acid diethylamide, cocaine, and heroin are all increasingly obtained illegally. Those who start obtaining drugs illicitly, and become addicted, commonly have a severe personality disorder. They may experiment with any drugs they can obtain.

Sources of Drugs

Heroin and cocaine, each of which has been sold for £1 for 60 mg. for the past ten years, appear to originate from legitimate prescriptions for other addicts who do not always use the amount prescribed. Cannabis (marihuana), commonly known as "pot," "weed," or "hemp," is increasingly widely smoked, and not only by recent immigrants. People generally smuggle it into the country in small amounts for themselves and their friends, though some appears to be smuggled for profit.

Amphetamines and amphetamine-barbiturate combinations are sold widely in capsule and tablet form for 1s. to 2s. each in cafés under such names as "purple hearts," "french blues," or "black bombers." The price is higher at weekends when the demand by young people to become "high" or "blocked" is greater. These have probably been stolen in bulk or otherwise diverted at some stage after manufacture. The current source of L.S.D. is less certain, but until very recently it was legal both to import and to possess the drug.

Control of Drugs

The control of drugs which are liable to be misused is carried out on behalf of the Home Secretary and of the Secretary of State for Scotland by inspectors and other officers. There is a widespread belief that there is a group of addicts who have become "registered," and thus entitled to an indefinite free supply of drugs. This myth is widely fostered by addicts themselves, who often tell doctors that they are "registered," implying that they are entitled to have drugs.

Drugs controlled under the existing Dangerous Drugs Acts may in fact be prescribed by any registered medical practitioner for anyone, and the Home Office index or register is only a list of persons known to be addicted to narcotic drugs. This is chiefly compiled from the routine inspections by the police of retail pharmacists' registers. When, after investigation, cases of drug addiction are found the names are added to the index. The police notify all cases of drug addiction they find, and prisoners who are addicts are also reported. The Home Office also obtains some information from hospitals, doctors, social workers, and similar sources.

Drug Dependence

The new term "drug dependence" is a general term applicable to all types of drug abuse. It is a state of psychic or physical dependence, or both, which may arise after long-term administration of a drug. Describing the type of dependence is an integral part of the new terminology (morphine-type, cannabis-type, amphetamine-type).

TABLE I.—*Summary of Statutory Provisions for Control of Drugs*

	Dangerous Drugs Act (1965) and Dangerous Drugs (No. 2) Regulations (1964)	Drugs (Prevention of Misuse) Act 1964	Pharmacy and Poisons Act 1933, Poisons List Order 1966, and Poisons Rules 1966
Drugs controlled	Opiates Morphine Heroin* Methadone Synthetic analgesics Pethidine, etc. Cocaine* Cannabis*	Amphetamines* and some similar substances Lysergic acid diethylamide (L.S.D.25)* and some similar substances, including mescaline	Barbiturates Many other substances are controlled under these provisions, including drugs controlled under the Dangerous Drugs Act and the Drugs (Prevention of Misuse) Act
Main provisions	(*a*) Offence to possess without authority	(*a*) Offence to possess without authority	(*a*) No offence to possess without authority, but substances in Schedule IV may be sold only by an "authorised seller of poisons" on a prescription from a duly qualified practitioner
	(*b*) Drugs to be kept under lock and key by authorized persons	(*b*) Drugs need not be kept under lock and key	(*b*) Drugs need not be kept under lock and key
	(*c*) Authorized persons have to keep records of drug movements	(*c*) Authorized persons need not keep records of drug movements	(*c*) No records of drug movements, except private prescriptions, have to be copied in prescription book
	(*d*) Offence to import and export except under licence	(*d*) Offence to import except under licence	(*d*) No restrictions on import or export
Penalties	Summary—£250 fine and/or 12 months' imprisonment Indictment—£1,000 fine and/or 10 years' imprisonment	Summary—£200 fine and/or 6 months' imprisonment Indictment—unlimited fine and/or 2 years' imprisonment	£50 fine

* Drugs commonly obtained illegally.

People can become dependent on a wide variety of chemical substances that produce central nervous system effects varying from stimulation to depression. When psychic dependence develops there is a feeling of satisfaction and a drive that requires periodic or continuous use of the drug to produce pleasure or avoid discomfort ("craving"). Some drugs also produce physical dependence, which is an adaptive state that shows itself by intense physical disturbances when the drug is stopped or its action affected by a specific antagonist (withdrawal or abstinence syndromes).

---

* Consultant Psychiatrist, Tooting Bec Hospital, London.

Marihuana

Marihuana is found in this country either as clippings from the dried flowering or fruiting tops of the cannabis plant or in the form of a resin extracted from it, often referred to as "hash," and a more potent source of the active ingredients (probably tetrahydrocannabinols).

When marihuana is smoked there is initially apparent stimulation and exhilaration, followed by sedation, depression, drowsiness, and sleep. The effects, however, are very variable and unpredictable. The neurophysiological effects are clumsiness, incoordination, and frequently ataxia. There may be analgesia of the skin, flushing of the face, pupillary dilatation, and a rise in the pulse rate and blood pressure.

The effects on mood vary from extreme elation and exhilaration to depression, panic, and severe anxiety. In general marihuana promotes a sense of well-being and relaxation. Anxiety and emotional tension may be reduced and critical faculties inhibited. It may induce striking illusions and hallucinations. The distortion of time perception is especially marked, and time appears to pass more slowly. Fantasy and imagination may be stimulated. Ideas may be plentiful but disconnected and disorganized. There may be increased auditory acuity and sensitivity to rhythm. Listening to music after taking the drug may produce unusual aesthetic responses. In general the drug produces an alteration in consciousness and an altered way of feeling and reacting to sensory stimuli. Marihuana is less effective as an analgesic than the opiates and produces less euphoria. Physical dependence does not develop. Like alcohol, but producing more euphoria, it is sought chiefly for casual recreational use and as an escape from reality. The experiences are often described as being "blocked" or "stoned."

The use of marihuana does not in itself cause any mental or physical ill health, though it may lead to social and legal problems. For example, it can be extremely dangerous to drive a car under the influence of marihuana, owing to altered perception.

Amphetamines

Amphetamines and amphetamine-barbiturate compounds are usually taken at weekends by adolescents to produce euphoria and wakefulness, and to increase energy and talkativeness. Occasional weekend use has been called "benign" compared with a "malignant" use, where psychological dependence on amphetamines has developed.

People in this group take more, and are inclined to use a variety of forms of amphetamine in a reckless manner. They start taking the drug during the week as well as the weekend, and their physical health and work suffer. They often have short-lived mental illnesses, which may lead to hospital admission because of agitation, restlessness, and schizophrenic-like psychoses, frequently with persecutory ideas. They may develop depressive reactions ("coming down") when they stop the drug. These are sometimes described as "the horrors" (though this term is also used for the acute psychotic illnesses).

Amphetamines may be taken intravenously by heroin addicts as an alternative to cocaine. Psychological dependence on amphetamine is also seen in patients who first have it prescribed as an antidepressant or appetite suppressant.

Lysergic Acid Diethylamide

Short-lived psychoses are also seen in people who have taken the drug lysergic acid diethylamide (L.S.D.25). It is a potent drug which one would have thought unlikely to be widely misused, because tolerance often develops rapidly while dependence (psychological or physical) does not develop. Also its effects are uncertain and can be exceedingly unpleasant. Nevertheless, it is now widely used (or misused) in the United States and to some extent here. The view that L.S.D. is harmless and safe is not supported by the figures of untoward reactions. Common complications are psychotic reactions with hallucinations, anxiety—which can amount to severe panic—depression, and confusional episodes with disorientation. These may occur at the time the drug is taken, and may sometimes recur, particularly under stress, for several weeks after. Judgement may be so disordered that a person may believe that it is possible and safe to float down from a height.

A patient with acute adverse reactions should be admitted to hospital and treated with intramuscular chlorpromazine.

Heroin and Cocaine

Drug addiction of the morphine type is more serious, because it is more difficult to treat. It is seen increasingly frequently among young people who take heroin, usually combined with cocaine, by intravenous self-administration ("main-lining"). The common pattern is for someone who has previously taken other drugs to experiment with heroin, taking it occasionally subcutaneously or intramuscularly ("skin-" or "joy-popping"). He then takes it more regularly, and finally daily and intravenously. Physical dependence is likely to develop at this stage and may parallel the development of tolerance. When an addict cannot afford enough of the drug to avoid withdrawal symptoms he may try to get drugs prescribed for him by explaining his predicament to a doctor, who (if he believes that maintenance of the addiction is the best treatment) may do so.

Heroin addicts may also seek treatment for a physical illness. Unsterile self-injection with shared syringes can lead to serum hepatitis, multiple abscesses, subacute bacterial endocarditis, or septicaemia. A common emergency is an overdose, and this is the commonest cause of death.

Though the treatment of an overdose is straightforward (resuscitation: artificial respiration, cardiac massage) there are some special problems. If morphine antagonists (such as nalorphine) are used as an antidote the patient will have severe abstinence symptoms when he recovers consciousness, and a further dose of the opiate may be needed to counteract withdrawal. This is clearly undesirable when treating overdosage. Many of these patients have taken cocaine simultaneously, and this may cause ventricular fibrillation. Addicts who take cocaine may also develop short-lived psychoses similar to amphetamine psychoses.

Addicts are apt to be untruthful. The story of a person who states that he is a heroin addict "registered" at the Home Office, that his own doctor is on holiday, and that he is suffering from withdrawal symptoms should be checked. If there are multiple antecubital puncture marks, abscess sites, and tattooing of the veins it is probable that intravenous heroin has been taken. If drugs have been prescribed it is possible, by contacting either the drugs department of the Home Office or the doctor who prescribed or the chemist who dispensed the drug, to confirm what has been prescribed or dispensed.

Treatment of Withdrawal Symptoms

The early signs of opiate withdrawal are craving for drugs, anxiety, restlessness, and running of the nose. These and more serious abstinence signs are shown in Table II. The symptoms are unpleasant but not usually dangerous, and their onset is gradual. It is unnecessary to give heroin immediately to every addict who demands it, and it is always undesirable to give a prescription to an addict who has not been seen before. Treatment is indicated for a known physically dependent addict who is genuinely distressed, has not had any heroin for at least six hours, and is developing withdrawal symptoms. Treatment should be in hospital if possible.

TABLE II.—*Times of Appearance of Abstinence Signs in Physically-dependent Opiate Addicts**

Grade of Abstinence	Signs	Hours After Last Dose		
		Heroin	Morphine	Methadone
0	Craving for drugs, anxiety	4	6	12
1	Yawning, perspiration, running nose, lacrimation	8	14	34–48
2	Increase in above signs plus mydriasis, gooseflesh (piloerection), tremors (muscle twitches), hot and cold flushes, aching bones and muscles, anorexia	12	16	48–72
3	Increased intensity of above plus insomnia, increased blood pressure, increased temperature, increased respiratory rate and depth, increased pulse rate, restlessness, nausea	18–24	24–36	
4	Increased intensity of above plus febrile facies, position (curled up on hard surface), vomiting, diarrhoea, weight loss, spontaneous ejaculation or orgasm, haemoconcentration, leucocytosis, eosinopenia, increased blood sugar	24–36	36–48	

* Modified from a Table by P. H. Blachly, *Amer. J. Psychiat.*, 1966, **122**, 742.

There is no physical dependence on cocaine, so there is no need ever to prescribe or administer it. Heroin withdrawal symptoms can be treated equally well with morphine or methadone (Physeptone). The best way is to use oral methadone, preferably in linctus form so that the patient does not know the amount he is given.

The equivalent in other opiates of methadone 1 mg. are: heroin 1 mg.; morphine 3 mg.; pethidine (meperidine) 20 mg.; codeine 30 mg.; and laudanum (1% morphine) 0.3 ml.

Methadone itself is a drug of addiction and physical dependence to it develops, but withdrawal symptoms are milder. In a doubtful case methadone 10 mg. could be given, and 20 mg. an hour later if there is no improvement. This could be repeated after a further two hours, but 50 mg. should be adequate to cover the next 12 hours, while other arrangements for treatment were made.

Some patients may be dependent on more than one drug. Some take all their prescribed heroin in the morning and barbiturates in the afternoon and evening, when heroin withdrawal symptoms occur. After a time physical dependence on barbiturates develops.

Addicts overstate the dose of opiates they take and underestimate sedatives. A heroin addict can die from inhalation of vomit during a fit from barbiturate withdrawal while being treated for heroin withdrawal symptoms, if concurrent physical dependence on barbiturates is not suspected. Where large amounts of heroin have definitely been taken more methadone will be needed.

Barbiturates

Physical dependence on barbiturates may be found in alcoholics as well as heroin addicts. It may also be found in those who take large amounts of amphetamine-barbiturate combinations. The commonest cause, however, is excessive prescribing of barbiturates as sleeping tablets. The effects of large doses include ataxia, dysarthria, impairment of mental function, confusion, loss of emotional control, poor judgement, and, occasionally, a toxic psychosis. Coma and death may occur.

When physical dependence on barbiturates has developed and the drug is suddenly stopped, the withdrawal symptoms include, in the approximate order of appearance, anxiety, involuntary twitching of the muscles, tremor of hands and fingers, progressive weakness, dizziness, distortion in visual perception, nausea, vomiting, insomnia, loss of weight, a precipitate drop in blood pressure on standing, convulsions of a grand mal type, and a delirium resembling alcoholic delirium tremens or a major psychotic episode. Convulsions and delirium do not usually occur at the same time. Generally a patient may have one or two convulsions during the first 48 hours of withdrawal and then become psychotic during the second or third night.

The barbiturate withdrawal syndrome is best treated in hospital with barbiturates alone. The degree of tolerance must first be determined, by systematically adjusting dosage until intoxication develops, to prevent the development of convulsions from premature withdrawal. Next the physical dependence must gradually be decreased. Physical dependence on barbiturates and other sedative hypnotics (glutethimide, diazepam, chloral) is more severe and dangerous than opiate dependence, and more easily overlooked.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Pigmented Naevi in Children

Q.—*Three days after surgical excision of a non-malignant pigmented naevus a child aged 6 developed 10 small pigmented naevi over her trunk. Is this unusual or significant?*

A.—Melanocytic naevi are common skin tumours and tend to appear clinically during infancy and childhood. It is tempting to suggest that in the case in question the 10 pigmented naevi had escaped detection before operation, but they might well have become manifest rather rapidly during an active phase of pigmentation. Whether the "stress" of minor surgery had accelerated this process is a matter for speculation.

The occurrence is unusual but not of any sinister significance, since malignant change in a pigmented naevus is an extreme rarity before puberty. A comprehensive review of juvenile melanoma can be found in the *Year Book of Dermatology.*[1]

REFERENCE

[1] Kopf, A. W., and Andrade, R., *Year Book of Dermatology*, 1965–66. Chicago.

Smallpox Vaccination and D.T.P.

Q.—*It is now recommended that D.T.P. and oral polio vaccine be given at the age of 2 to 6 months, and that a booster dose of these prophylactics should be given at 18 months. Is it advisable to vaccinate against smallpox when giving the booster doses at 18 months?*

A.—Simultaneous administration of D.T.P. and live smallpox vaccines does not affect the antibody response to the diphtheria, tetanus, or smallpox vaccines, but the small risk of encephalitis, which is associated with both pertussus and smallpox vaccines, may be greatly increased if they are given at the same time. It is therefore advisable to allow at least three weeks to elapse between the administration of D.T.P. and smallpox vaccines.

Insulin by Aerosol

Q.—*Has the possibility of administering insulin by metered aerosol inhalation been explored?*

A.—I am not aware of any recent work on administration of insulin by aerosol. Such routes as the oral, lingual, nasal, vaginal, and rectal have been tried,[1 2] but, though absorption of insulin was demonstrated in some cases, none has proved an acceptable alternative to the parenteral route. Nasal and pulmonary absorption could not be unequivocally proved.[2]

Book Reviews

Organ Transplantation

Advances in Surgery. Vol. 2. Edited by Claude E. Welch. (Pp. 520; illustrated. £6 12s.) London: Lloyd-Luke. 1967.

One of the truly remarkable phenomena of advances in surgery during the past handful of years has been the explosive development of organ transplantation. This aspect of medicine is of interest not only because of the future possibility of being able to replace any diseased or worn out organ, but also because of the flood of information revealed by clinical and experimental research in the immensely difficult struggle towards this target. Each of the three basic problems in this field—the storage of transplant organs, the pre-operative improvement and then post-operative maintenance of the patient dying of impairment of some vital structure, and the prevention or suppression of the immune rejection process—has evoked quite remarkable advances in fundamental biological knowledge and in practical clinical progress. One may quote tissue typing as an example of the former and progress in extracorporeal liver perfusion in the latter category.

A reflection of the speed of progress in transplantation is the fact that the whole of the second volume of a new series termed "*Advances in Surgery*" has been devoted to this one subject. It is notable that the contributors (apart from Professor Woodruff, who writes the introduction) are all representatives of surgical departments in the U.S.A.—a tribute both to the important part that surgeons have played in this field and to the debt which we owe to the American university medical centres with their lavish equipment and dedicated investigators for many of the major developments in this subject.

The range of topics is comprehensive. There are sections on fundamental studies in leucocyte- and tissue-typing and of immune mechanisms. Experimental work is detailed in the fields of endocrine, gastrointestinal, hepatic, cardiac, and kidney transplantation, as well as experimental limb replantation. Clinical chapters deal with experience in what has already been achieved in organ transplantation in man, notably in kidney grafting (skilfully reviewed by Dr. David Hume), but also describing successful homografting of the parathyroid in hypoparathyroidism and the first attempts at human liver and lung transplantation. There is also an interesting chapter on human upper limb replantation.

This volume can be recommended to any surgeon who wishes to consult an up-to-date and readable account of the field of surgical transplantation. The contributors include most of the surgical leaders in this field in the United States. Most of the chapters have useful summaries and all include exhaustive and up-to-date bibliographies.

HAROLD ELLIS.

Keeping Up with Medicine

The Medical Annual. 84th Year. 1966. Edited by Sir Ronald Bodley Scott, K.C.V.O., M.A., D.M., F.R.C.P., and R. Milnes Walker, C.B.E., M.S., F.R.C.S., F.A.C.S.(Hon.). (Pp. 667+xxxv; illustrated. 52s. 6d.) London: Longmans, Green. 1966.

The form of the 84th issue of this popular annual remains much the same. Nine new names appear, but the true increase in contributors is from 45 to 48, since some are replacements of those who have given up from retirement and other causes (but happily not death).

A review of the year's work occupies most of the book and contains two new sections. Under geriatrics, Dr. A. N. Exton-Smith discusses the current problems of psychogeriatrics and accidental hypothermia, and under general practice Drs. J. H. Hunt and M. J. Linnett (both general practitioners) consider measles prophylaxis and some simple, rapid, pathological tests. Each summary is followed by references and some have editorial comment as well.

The four special articles will be of interest to all doctors. F. T. de Dombal and G. Watkinson conclude that most patients with ulcerative colitis can be kept in reasonable health on medical treatment alone but that surgery is indicated for intractable severe attacks and for patients, especially elderly ones, with total involvement. Multiple sclerosis (the term for disseminated sclerosis now regretfully accepted) is the subject of an excellent review by Professor Henry Miller, who in characteristic style hits out against the professional irresponsibility of much published work about it. Professor A. J. H. Rains's known interest in gallstones is compressed into a most interesting article and the newest ideas about wound healing are discussed by Mr. D. M. Douglas.

Dr. R. M. Mason's usual excellent review on the chronic rheumatic diseases contains up-to-date statements on polymyalgia rheumatica and colitic arthritis. Dr. Oliver Garrod summarizes the work on multiple endocrine adenomatosis, the sex hormones, and on auto-immunity linking endocrine disorders. The section on alimentary disease is the combined work of five distinguished authors, among whom are Professor Sheila Sherlock and Dr. F. Avery Jones. The abandonment of gastric freezing, the Mallory-Weiss syndrome, and Trasylol are among the subjects discussed. The reader will find concise statements on many other current topics, too numerous to mention in detail, such as tetanus prophylaxis, dehydration, osteoporosis, and stereotactic surgery for pain. Among all the specialties, there would seem to be little left under general medicine, but Dr. J. E. Cates has dealt interestingly with his chosen subjects: systemic lupus erythematosus, march haemoglobinuria, and hypercalciuria. The list of "Books of the Year" and the "Practitioners' Index of Drugs and Appliances" are both features which deserve perusal.

Since this book deals with many subjects, it is not to be looked upon as an annual refresher course in any one specialty or a guide to the examination for some special diploma. It is rather an annual presentation of what has recently happened in many fields of medicine and surgery and is a convenient way of keeping the busy doctor "clued up" on the rest of the medical world. It is highly recommended for a place on every doctor's bookshelf.

C. ALLAN BIRCH.

Approach to Old Age

Practical Management of the Elderly. By W. Ferguson Anderson, O.B.E., M.D., F.R.C.P.(Glasg., Edin., Lond.). (Pp. 304 +vii; illustrated. 50s.) Oxford: Blackwell. 1967.

This volume, slim in comparison with the size of the field that it covers, is a welcome addition to the literature on geriatrics. Geriatric trainees and general practitioners will find it of great value.

Professor Anderson's book achieves coverage of the whole field of geriatrics by assuming a sound knowledge of general medicine but concentrating on those aspects of medicine which are specially important in the aged. This is, after all, in accord with the enlightened view of geriatrics, which is the application of general medicine in all its branches to the aged. Since the aged suffer mainly from degenerative disease, he rightly begins with the preventive approach, including a special chapter on work and retirement. Since the object of treatment of the elderly sick is to re-integrate them into society, he then follows with an account of the services available for the elderly.

The main body of the book consists of a consideration of the diagnosis and treatment of disease in the aged, organ by organ, and it is here that space is saved by assuming a sound knowledge of general medicine. At the end is a short appendix on teaching geriatrics and training geriatric physicians which is of great interest because so little has been written on this subject, and most appropriate, coming as it does from the only professor of geriatric medicine in Great Britain.

Throughout the book Professor Anderson clearly speaks of what he knows from personal experience. This is no random collection of other people's thoughts, though his frequent references will be most useful to those who wish to extend their reading of the subject. His pungent and highly personal style of writing is refreshing in these days when it is fashionable to write as if one were a scientific robot; it will hold the reader's interest to the end of the last chapter.

E. WOODFORD-WILLIAMS.

Brain Research

Correlative Neurosciences. Part A: Fundamental Mechanisms. Progress in Brain Research. Vol. 21A. Edited by T. Tokizane and J. P. Schadé. (Pp. 363+xi; illustrated. £5 15s.) Amsterdam, London, and New York: Elsevier. 1966.

Correlative Neurosciences. Part B: Clinical Studies. Progress in Brain Research. Vol. 21B. Edited by T. Tokizane and J. P. Schadé. (Pp. 437+xi; illustrated. £7 5s.) Amsterdam, London, and New York: Elsevier. 1966.

In neurophysiology Japanese workers have made many important contributions, and the manual skill for which they are renowned has made them leaders in some of the most refined investigations, entailing dissection of single nerve units. These two volumes, which contain only articles from Japan, indicate that excellent work in every branch of the neurological sciences is being done in that country at the present time. The first volume contains studies in the basic sciences, while the second is concerned with clinical studies and the applied aspects of physiology, pharmacology, and anatomy. Taken together they cover a wide field of endeavour.

It is of interest to note how much of the basic neuroanatomy and neurophysiology presented in Part A is concerned with functional organization of dendrites. Thus Furakawa, in discussing the functional characteristics of the multitude of synapses on the Mauthner cell of the goldfish, is considering the interaction of post-synaptic events generated at regions of the cell surface which are separated by several hundred microns. And Mannen, presenting some of the most elegant illustrations of neuronal morphology ever published, is attempting to give a quantitative account of the branching of dendrites and the relation between dendritic and somatic surface areas. If applied to many regions of the nervous system, this could provide a most valuable structural basis for physiological theory.

The review by Katsuki of the neural mechanisms of hearing in cats and monkeys is very clear. There are also reports of studies of the central mechanisms of vision and cutaneous sensation as investigated with electrophysiological and anatomical techniques. Brain metabolism and histochemistry, autonomic functions of hypothalamic centres, and studies of neuronal events in relation to the E.E.G. complete the list of topics covered in the basic science section.

Part B is more difficult to review because clinical trials, epidemiological studies, and results of surgical lesions in patients are presented along with experimental investigations of electrical seizure activity in hippocampal tissue, of cortical stimulation in cats, and of paradoxical sleep in rabbits, cats, and man. Yet the reader is impressed by a serious attempt by these Japanese doctors and scientists to use all the methods of study which are available, from classical injection techniques for making anatomical casts of blood vessels in patients who have died of strokes to biochemical studies of central neurones and electrophysiological recording with microelectrodes inside single nerve cells. Pharmacological studies, behavioural studies, and electrical recordings are often used in combination. These researches, approaching many different problems in the neurological sciences from many different points of view, do seem to have some relevance to the study and understanding of clinical neurological problems. This relevance is emphasized by the method of presentation of the chapters in Part B of this work, where the different reports are intermingled.

The articles are beautifully presented, and some of the illustrations are of very high quality. The Progress in Brain Research series is now reaching an impressive size. But the volumes are expensive.

ROBERT PORTER.

Personal View of Paediatric Pathology

Pediatric Pathology. 2nd edition. By Daniel Stowens, M.D. (Pp. 847+ xi; illustrated. £10 12s.) Edinburgh and London: E. & S. Livingstone. 1966.

This book sets out a personal lifetime's experience of paediatric pathology. Although in the preface to the second edition the author says the book is written primarily for doctors who care for and care about sick children, there is no doubt that what he says in the preface to the first edition—that pathologists show an unfamiliarity with the problems of paediatrics—is still true. Therefore the ordinary pathologist should be able to obtain the answer to many of his problems from such a book.

The author deliberately retains in the second edition the emphasis on the morbid anatomical approach to disease. This is unfortunate because so much more could be learnt from a more modern comprehensive approach. While it is true that many of the diseases are reflected in anatomical changes, it is almost impossible to discuss, as he does in so many places, the effects of biochemical change without discussing in more detail the actual biochemical findings. This is particularly true of the nutritional and deficiency disorders as well as in the chapters on the inborn errors of metabolism. In the diseases associated with bacteria there are brief paragraphs included on the morphology of the bacteria. These are really quite useless, as seen in the introductory paragraphs to meningococcal and pneumococcal infections.

In a more original approach the author has transferred the chapter on leukaemia from blood disorders and has placed it into the section dealing with diseases associated with chromosomal abnormalities. This was deliberate but surely unwarranted, and it is unfortunate that paediatricians should be given this impression with leukaemia occupying 13 pages, including almost full-page photomicrographs of kidney infiltration, when Down's syndrome (Mongolism) is dealt with in two pages. (The author has felt impelled to use here nine photomicrographs showing various forms of infiltration from a paper read by him in 1961.) In the inborn errors of metabolism, too, the abnormal haemoglobins, congenital spherocytosis, and Mediterranean anaemia are all introduced in very short sections. All would be better placed in the otherwise very limited chapter on diseases of the blood.

As this book represents the author's own tremendous experience it is inevitable that certain chapters will be extensive at the expense of others. For this reason it will not satisfy the paediatric pathologist as a book of reference. For example, the embryology of congenital malformations of the genitourinary tract, which comprise 30% of all congenital malformations, is dealt with essentially as anomalies of the kidneys, but bladder-neck obstruction in the male, which is certainly of increasing interest, is dealt with in one paragraph.

Nevertheless, it is unfair to criticize this book adversely. It contains an enormous wealth of material, is beautifully produced with excellent photomicrographs and particularly good electron microscope photographs of a renal biopsy, is well arranged, and has an excellent bibliography with easily found references.

The cost of over £10 may, unfortunately, mean that it will be bought by the libraries but probably not by many individual pathologists.

Genetics of Neurological Disorders

Humangenetik. Vol. 5/1. Krankheiten des Nervensystems. Edited by P. E. Becker. (Pp. 557+xii; illustrated. DM. 174.) Stuttgart: Georg Thieme. 1966.

The high standard of the three volumes of this handbook of human genetics already published is more than maintained by this treatise on the genetics of the neurological disorders. In contrast with the multiple authorship of the earlier volumes, this text is the work of the editor, Dr. P. E. Becker, and only one associate. Dr. Becker contributes three extensive sections which deal systematically with the disorders of the cerebellum and the nervous system below the thalamus. Dr. G. Koch deals equally fully with the diffuse scleroses, the phakomatoses, and various extrapyramidal disorders (such as Huntington's chorea, Parkinson's disease, and nystagmus), and in a concluding chapter with a variety of ill-defined affections.

The text is beautifully illustrated and is supported by exhaustive lists of references, which by themselves are exceedingly valuable, as they are arranged by clinical groupings. The lists on rare affections are particularly admirable. Encyclopaedic in range, the volume carries discussions which are frequently in the nature of monograph surveys based on personal work by the two authors. Because of its comprehensiveness and critical insight into a diffuse and particularly difficult literature this volume is likely to establish itself as the standard work on the subject.

ARNOLD SORSBY.

Hallucinatory Drugs

The Varieties of Psychedelic Experience. By R. E. L. Masters and Jean Houston. (Pp. 326. 84s.) London: Anthony Blond. 1967.

R. E. L. Masters, who is a popular and prolific American writer on matters of sex, has now joined his wife, Jean Houston, in producing a book on an even more immediately topical subject. It discusses their findings in over ten years of giving the psychedelic drugs to a wide variety of people. Then it became illegal in the U.S.A. for L.S.D. to be given or used without medical supervision. Their work has therefore stopped, as neither of the authors is a qualified doctor.

The book does little more than tread all the old ground of those doctors who, for the past 30 years or more, have tested these drugs experimentally and therapeutically, and have recorded their good and bad phenomena and side-effects. Only very limited therapeutic benefits have been obtained. Most of the people given the drug and discussed in this book must come under the heading of "normal," but in the widest range of its meaning. The authors attach great importance to the role of the so-called "guide," who stays with the patient and helps to control what is experienced by the subject under the drug. The guide directs the delusional and hallucinatory material into what are thought to be the best insight channels for each individual. L.S.D., mescaline, and the like are probably the most useful drugs for imposing on others the lessons we feel they need to learn. If the guide is interested in birth trauma most of his subjects tend to obtain startling experience of it. Many will interpret any experiences they get under the drug along such lines—or along Freudian or Jungian lines if that is their guide's own speciality.

The book does not tell us when these drugs should and should not be used, and it gives no advice on the handling of the psychiatric emergencies that are bound to arise. The results of giving hallucinatory drugs, as recorded in this book, remain as speculative as ever in terms of human benefit, especially to those still unconvinced that they do anything but create new delusions and hallucinations for the patient, and mainly serve to encourage abreaction about what is being experienced or supposedly remembered. Moreover, present guides, with their own special beliefs and viewpoints, are rarely the ones best equipped to sort the true from the false.

WILLIAM SARGANT.

Books Received

Review is not precluded by notice here of books recently received.

Symposia Series in Immunobiological Standardization. Vol. 3. International Symposium on Biotechnical Developments in Bacterial Vaccine Production. Edited by R. H. Regamey, H. Hennessen, D. Ikic, and J. Ungar. (Pp. 240 +xii; illustrated. sFr./DM. 52.50.) Basel and New York: S. Karger. 1967.

Nursing Mathematics. By Margaret Rosier, S.R.N., H.V., A.I.H.E. (Pp. 242; illustrated. 13s. 6d.) London: Oxford University Press. 1967.

Principles of Head and Neck Surgery. By H. Robert Freund, M.D., with six contributors. Illustrated by Gottfried W. Goldenberg. (Pp. 337+xi; illustrated. $12.50.) New York: Appleton-Century-Crofts. 1967.

Pesticides and Pollution. The New Naturalist Series. By Kenneth Mellanby. (Pp. 221; illustrated. 30s.) London: Collins. 1967.

Clinical Judgment. By Alvan R. Feinstein, M.D. (Pp. 414+vii; illustrated. 76s.) Edinburgh and London: E. & S. Livingstone. 1967.

Childbearing. Its Social and Psychological Aspects. Edited by Stephen A. Richardson, Ph.D., and Alan F. Guttmacher, M.D. (Pp. 334 +xvii. 68s.) Edinburgh and London: E. & S. Livingstone. 1967.

Roentgen Diagnosis of Diseases of Bone. By Jack Edeiken, M.D., and Philip J. Hodes, M.D. (Pp. 701+v; illustrated. £12 16s.) Edinburgh and London: E. & S. Livingstone. 1967.

Comprehensive Textbook of Psychiatry. Edited by Alfred M. Freedman, M.D., and Harold I. Kaplan, M.D. (Pp. 1666+xxv; illustrated. £9 18s.) Edinburgh and London: E. & S. Livingstone. 1967.

Textbook of Gynecelogy. 4th edition. By John I. Brewer, B.S., M.D., Ph.D., and Edwin J. de Costa, B.S., M.D. (Pp. 918+xxviii; illustrated. £6 16s.) Edinburgh and London: E. & S. Livingstone. 1967.

Medical Shorthand. By Phyllis E. Davis and Nancy V. Hershelman. (Pp. 317+ix. 50s.) London: John Wiley. 1967.

Lectures on Preventive Cardiology. By Jeremiah Stamler, M.D. (Pp. 434+xiv; illustrated. $18.75.) London and New York: Grune & Stratton. 1967.

Nutrition. By Rudolf Hauschka, D.Sc. Translated from the German by Marjorie Spock and Mary T. Richards. (Pp. 212+xi; illustrated. 55s.) London: Stuart & Watkins. 1967.

Molecular Basis of Some Aspects of Mental Activity. Vol. 1. Edited by Otto Walaas. (Pp. 476+xv; illustrated. £5 10s.) London and New York: Academic Press. 1967.

Molecular Basis of Some Aspects of Mental Activity. Vol. 2. Edited by Otto Walaas. (Pp. 515+xv; illustrated. £6 6s.) London and New York: Academic Press. 1967.

Pathologic Physiology. Mechanisms of Disease. 4th edition. By William A. Sodeman, M.D., Sc.D., F.A.C.P., and William Sodeman, jun., M.D. (Pp. 1051+xxi; illustrated. £6 13s.) London: W. B. Saunders. 1967.

The Vesico-Vaginal Fistula. 2nd edition. By J. Chassar Moir, C.B.E., M.D.Edinb., M.A.Oxon., D.M.Oxon., F.R.C.S.(Edinb., F.R.C.O.G., Hon. LL.D. Queen's University, Ontario, Hon. M.M.S.A. (Pp. 196+ix; illustrated. 60s.) London: Baillière, Tindall & Cassell. 1967.

The Use of Antibodies in the Study of Blood Coagulation. By K. W. E. Denson, D.Phil. (Oxon.). Foreword by R. C. MacFarlane, C.B.E., M.A.(Oxon.), M.D.(Lond.), F.R.S. (Pp. 244+ix. 52s. 6d.) Oxford: Blackwell. 1967.

Neurosis in the Ordinary Family. A Psychiatric Survey. By Anthony Ryle, D.M. (Pp. 155. 32s. 6d.) London: Tavistock. 1967.

Histologie und Zytologie des Menschen. Einführung für Ärzte und Studenten. By Professor H. Leonhardt. (Pp. 407+viii; illustrated. DM. 10.80.) Stuttgart: Georg Thieme. 1967.

Clinical Virology: A Year's Experience

J. E. BANATVALA,* M.A., M.D., M.C.PATH., D.P.H., D.C.H.; ELIZABETH A. KENNEDY,* B.A.(MOD.)
JENNIFER M. BEST,* B.SC.

Brit. med. J., 1967, 3, 609–612

Advances in virology over the last decade, mainly resulting from the renaissance of tissue culture techniques and the application of these techniques to the field of diagnostic virology, have led to the discovery of many viruses which have been shown to cause infectious disease.

Hitherto, most diagnostic virology in England and Wales has been performed by the Public Health Laboratory Service. However, the increasing demand for virological investigations has resulted in a few hospitals developing clinical virology laboratories of their own, and it seems possible that this trend may increase. It is important to evaluate such services from time to time in order to see whether or not a useful service is provided, to whom it is of value, and, almost equally important, for both clinicians and virologists to realize its shortcomings and recognize when certain types of investigation are uneconomic or of doubtful value.

This paper presents our first year's experience (21 January 1966 to 20 January 1967) in developing and running a clinical virology laboratory at St. Thomas's Hospital.

Organization and Function of the Laboratory.—The laboratory staff consists of a microbiologist (J. E. B.), assistant microbiologist (E. A. K.), research fellow (J. M. B.), two technicians, a glassware assistant, and a secretary. The function of the laboratory is to provide diagnostic services to the hospital, to conduct research into clinical and epidemiological problems associated with virus infections, and to train both graduates and technicians in diagnostic procedures and research methods. Studies on infection by rubella and herpes simplex viruses have been in progress during the course of the year, the results of which are being presented elsewhere.

Materials and Methods

Selection of Cases.—Patients with possible virus infection were referred for investigation. Before investigations were begun clinical details were discussed; then the microbiologist, whenever possible, visited the wards to see patients and obtain or advise on specimens to be collected. Outpatients were often referred from their respective clinics to the laboratory, where clinical details and specimens were obtained and visits for further specimens, if necessary, arranged.

Identification of Viruses

1. *Isolation.*—Specimens were prepared and processed immediately after arrival in the laboratory (Lenette, 1964), after which they were inoculated into tissue culture. Specimens were then "snap" frozen and stored at −70° C. Cultures of secondary rhesus monkey kidney (M.R.C. Hampstead) and suspensions of primary vervet (M.R.C. Hampstead) and patas monkey kidney cells (Wellcome Research Laboratories) were supplied regularly. In addition, HeLa, WI-38, and RK13 cell cultures were propagated in the laboratory. Reserves of these cells were kept frozen in liquid nitrogen (Linde LNR-25-B, Union Carbide). Rubella virus was detected by the appearance of cytopathic effect in RK13 cell cultures (McCarthy, Taylor-Robinson, and Pillinger, 1963) and the presence of interference phenomena in patas or vervet cell cultures (Parkman, Buescher, and Artenstein, 1962). Specimens from patients with possible enterovirus infections which failed to show cytopathic effect in tissue culture were inoculated into suckling mice in order to detect the presence of Coxsackie A viruses. The identity of all isolates was confirmed by neutralization tests employing virus-specific rabbit antisera. In addition, fertile hens' eggs and an agar-gel diffusion system were kept readily available for the investigation of patients with possible infection with variola virus.

2. *Serology.*—Sera from patients with respiratory infections were tested against the following antigens by complement fixation: influenza A, B, and C; adenovirus; respiratory syncytial virus; parainfluenza 1, 2, and 3 viruses; *Rickettsia burnetii*; psittacosis; and *Mycoplasma pneumoniae*. Overnight fixation at +4° C. was employed (Bradstreet and Taylor, 1962), a microtitre apparatus (Sever, 1962) being used. Antibody titres in sera from pregnant women exposed to or contracting rubella were determined by neutralization (Dudgeon, Butler, and Plotkin, 1964) and complement-fixation tests (Sever *et al.*, 1965). Sera from patients from whom enteroviruses were isolated were, whenever possible, tested for significant rises (fourfold or greater) in antibody titre to the particular virus isolated. Serological evidence of mumps infection was detected by complement fixation, and measles by both complement fixation and haemagglutination inhibition. During the time that influenza was epidemic (January and February 1966) patients with possible influenza virus infection who failed to show significant rises in complement-fixing antibody titre were tested by haemagglutination inhibition (A2Eng. 1964).

Results

From 306 patients referred for virological investigations 741 specimens were obtained. The following patients were excluded: those who were subsequently shown to have disease which was non-viral (13); those from whom adequate specimens were not obtained—for example, because of inability to obtain "convalescent" sera when a serological diagnosis was to be attempted (11); and those referred for estimation of antibody to rubella virus when exposed to possible rubella in early

pregnancy (17). Attempts at diagnosis were completed on 262 patients. An aetiological agent was identified in 96 (36.6%) of these cases. A diagnosis by virus isolation alone was made in 56 (58%) of the 96 cases, by serology in 19 (20%), and by both serology and virus isolation in 21 (22%). However, serum was not obtained from 38 of these patients who attended the departments of venereology and dermatology with vesicular lesions of the skin or mucous membranes caused by herpes simplex virus, nor from five infants with acute respiratory infection from whom respiratory syncytial virus (2 cases), adenovirus (2 cases), and parainfluenza 3 virus (1 case) were isolated.

Table I lists the viruses detected and the principal clinical syndromes with which they were associated. The number of patients referred by different hospital departments and the results of virological investigations on them are shown in Table II. The high proportion of patients referred by the venereology department was partly caused by a survey on patients with herpes genitalis. Herpes simplex virus was isolated from 28 (38%) of 73 patients with clinical herpes genitalis, no other virus being isolated. Though the clinical diagnosis of herpes genitalis may be simple enough when typical vesicles are present, once ulceration has occurred other conditions have to be differentiated. The most important of these is syphilitic chancre, but such diseases as chancroid, lymphogranuloma venereum, candidiasis, and Behçet's syndrome may also have to be considered. Concomitant serological tests (Wassermann reaction and Reiter's protein complement-fixation test) did not reveal any cases of primary syphilis in this series. The detailed results of this investigation are being published elsewhere.

Fifty-two members of the hospital staff, most of whom were nurses, were referred for virological investigation. The high incidence of infectious disease in general, and of acute respiratory and exanthematous disease in particular, is characteristic of communities of young adults living in close quarters. It was possible to obtain specimens from most of these patients within 72 hours of the onset of symptoms, this probably contributing toward the high diagnostic rate (46%) in this group. Rubella was prevalent among the nursing staff from March to April 1966. Since rubella often presents atypically and because of the relation between maternal rubella and congenital malformation, it was thought to be important to confirm the diagnosis of rubella virologically in nurses, not only for their own future reference, but also in order to exclude them from places where they might have contact with pregnant women (for example, children's wards, mothercraft clinics, etc.) until after the period of virus excretion—up to 14 days from the onset of rash (Krugman and Ward, 1964 ; Green *et al.*, 1965).

The paediatric department has 32 medical beds, but is also responsible for the care of newborn babies. A diagnosis was made on 20 (44%) of 45 cases investigated. The admission rate for acute respiratory infections, which is frequently high during winter, often coinciding with the prevalence of respiratory syncytial and parainfluenza viruses in the community (Chanock and Parrott, 1965), showed no marked increase during the winter months of the investigation. It is of interest that studies on 15 infants with congenital defects or neonatal infections revealed six cases of congenital rubella, five infants having many of the characteristic features of the rubella syndrome (Table III). These infants also possessed some of the additional features described as part of the "expanded" rubella syndrome noted after the large rubella epidemic in the U.S.A. in 1964 (American Pediatric Society and Society for Pediatric Research, 1965). Five of these six infants were of West Indian origin, there being a history of maternal rubella in only one of these cases. In hospital these infants were

isolated and tested for virus excretion at regular intervals. When at home, mothers were warned not to expose their infants to women who might be pregnant, until such time as tests showed that excretion had ceased. Nevertheless, one infant (Case 4) infected ten nurses during her stay in hospital. No virus other than rubella was recovered from any of the infants with neonatal infection or congenital malformation.

In relation to the number of beds available (298) a disproportionately small number of patients (53) were referred for investigation by the general physicians. Twenty of these patients had had symptoms for one week or longer, thereby making it difficult to be certain that any virus which was isolated was responsible for the patient's illness. Of the 11 patients in this group in whom serological evidence of infection was found or from whom virus was recovered, three had Bornholm disease, and from their stools E.C.H.O. 1 virus (two cases) and Coxsackie B2 virus (one case) were isolated. However, these patients showed neither rising nor elevated antibody titres to the respective viruses recovered, making the relation between virus isolation and illness tenuous.

A diagnosis was made in 19 patients with exanthematous disease (Table I). Generally, apart from cases of rubella, virus studies were not attempted on patients in whom clinical diagnosis was obvious, but only on those who presented a diagnostic problem; examples being a woman of 63 with a respiratory infection, high fever, and maculopapular rash who developed a significant rise in measles antibody titre during the course of her illness, and a child aged 6 months with fever and maculopapular rash from whose throat E.C.H.O. 16 virus was isolated.

Studies were conducted on 17 women exposed during early pregnancy to cases of possible rubella. Four of them were investigated within seven days of exposure, two having been exposed to a child with rubella while visiting their children in hospital. All of these patients were found to have neutralizing antibody to rubella virus, indicating previous infection. They were therefore immune to subsequent infection (Brody *et al.*, 1965; Green *et al.*, 1965). All but one of the remaining patients had neutralizing antibodies ranging from 1:8 to 1:32. However, these women presented at intervals ranging from four to eight weeks after exposure, making the interpretation of results difficult, since it was impossible to say whether their neutralizing antibody titre was acquired as a result of recent or of past infection. More recently, complement-fixation tests were performed in conjunction with neutralization tests, the presence of high titres of complement-fixing antibody being suggestive of recent infection (Sever *et al.*, 1965). Of four patients tested by both neutralization and complement fixation, none had complement-fixing antibody, suggesting that their neutralizing antibody was not a result of recent infection.

Discussion

In contrast to the position a decade or so ago, a virus diagnostic laboratory may be called upon to undertake investigations on an ever-increasing range of viruses. Thus facilities were provided, for example, for the detection of viruses causing acute respiratory and C.N.S. infections; viruses causing neonatal infections or congenital malformations—for example, rubella, cytomegalovirus, herpes simplex; as well as viruses responsible for exanthematous infections—for example, measles, variola, varicella/zoster, and enteroviruses. Such diagnostic procedures required the maintenance of numerous continuous cell-culture lines and the provision of a variety of serological techniques. Furthermore, the deployment of a small staff in both routine and research and the time involved in both seeing patients and discussing these cases with clinicians often imposed considerable strain on the laboratory's resources. Nevertheless, close co-operation between laboratory staff and clinical personnel proved invaluable, saving work in the long run by ensuring that good clinical material was selected for study and that correct specimens were obtained in the best possible condition with the minimum delay.

However, these factors necessitated some restrictions in the number and types of cases investigated. The 262 cases were investigated as a cost of approximately £40 per patient. A more economic figure could have been achieved only by carrying out a more limited range of investigations. An increase in the number of patients investigated or extension of services to neighbouring hospitals in our group would certainly have necessitated the provision of greater space and more personnel, or a regular supply of cell cultures ready for use from a commercial source. These factors would have entailed much greater expense.

Our experience over the past year demonstrated that the laboratory provided a useful service to certain hospital departments, whereas to others it was of less value than we had expected.

For example, virus studies which clinicians thought useful were the investigation of maternal and neonatal rubella, the diagnosis of atypically presenting exanthematous disease, and the differential diagnosis of vesicular lesions in patients referred by the dermatologists and venereologists. However, in contrast to many bacteriological investigations, most virological diagnostic procedures take a long time to complete, and the results can therefore seldom influence clinicians in the management of acutely ill patients. Furthermore, we found that investigations on many patients admitted to general medical wards who presented as "interesting" or "puzzling" cases with perhaps an unexplained fever or haematological features "consistent with viral infection" were usually unrewarding, since by the time such patients were admitted to hospital they were long past the acute phase of their illness, making either positive or negative virus isolation or serology difficult to interpret. Consequently, we investigated and obtained diagnoses on proportionately fewer patients referred by general physicians than on those referred from other departments in the hospital.

Most diagnostic laboratories dealing with large numbers of specimens are attached to the Public Health Laboratory Service, to hospitals for infectious diseases, or to children's hospitals, most of which, unlike our laboratory, can obtain large amounts of suitable clinical material from acutely ill patients. We believe that most value can be obtained from a laboratory such as ours, which is also an integral part of a research department of a teaching hospital, not by providing a fully comprehensive diagnostic service but by specializing in certain fields, working on them in depth, and training personnel in both diagnostic and research methods. General diagnostic services should mainly be restricted to cases where infectious disease provides an urgent public health problem or requires definite action (for example, smallpox, poliomyelitis, maternal and neonatal rubella), or is likely to prove genuinely useful to clinicians (for example, differential diagnosis of acute C.N.S. infections and atypically presenting exanthematous infection). Inevitably, in these circumstances the services of other laboratories would be required to perform additional tests which a small laboratory could not undertake.

Though many virological investigations are at present of limited value to clinicians, a clinical virology laboratory may profitably extend its studies to the investigation of the role of different agents in varying communities, thus "pin-pointing" specific public health and epidemiological problems. In addition, combined clinical and virological studies, conducted on carefully selected clinical material, are also likely to be rewarding if performed as well-defined projects. Though viral chemotherapy is not generally available today, the position may alter in the future. In such an event, increased sensitivity and diagnostic speed may well be essential, and clinical virology laboratories are particularly well placed to undertake work in order to achieve such aims.

Thus, in these ways clinical virology provides fields where routine and research work may profitably coexist hand in hand, much rewarding research stemming from properly collected specimens from well-documented cases.

Summary

A diagnosis was made on 96 (36.6%) of 262 patients referred for virological investigations between 21 January 1966 and 20 January 1967. The highest numbers of patients were referred by the departments of paediatrics and venereology and from the physician in charge of nurses' health. The highest diagnostic rates were achieved on those patients referred by the nurses' physician (46.4%) and by the paediatricians (44.4%). Investigations on women exposed to or contracting rubella in early pregnancy, on infants with congenital malformations or neonatal infections, and on exanthematous infections which presented atypically were thought to be among the most useful studies conducted. Difficulties encountered in providing a fully comprehensive diagnostic service are described, and emphasis is placed on the importance of conducting epidemiological, clinical, and virological studies on carefully selected material alongside routine diagnostic investigations.

We are grateful to the St. Thomas's Hospital Endowment Fund Committee and the Wellcome Trust for generous financial contributions; to Dr. C. M. P. Bradstreet, Standards Laboratory, Central Public Health Laboratories, Colindale, for supplying numerous serological reagents; to the Virus Reference Laboratory at Colindale and Epsom for typing various enteroviruses; and to the consultant staff of St. Thomas's Hospital for permission to investigate patients admitted under their care. One of us (J. M. B.) is in receipt of a grant from the M.R.C. in order to undertake research on rubella virus.

COMPUTERS IN MEDICINE

Notification of Death Occurring after Discharge from Hospital

M. R. HUBBARD*; E. D. ACHESON,† M.A., D.M., F.R.C.P.

Brit. med. J., 1967, 3, 612–613

Although the fact of death has been recorded in practically all instances in this country since the Registration Act of 1837, and a quarterly alphabetical index of persons dying is maintained at Somerset House by the Registrar General, it may still be difficult for a doctor to discover which of a group of patients treated by him has since died. This paper describes an experiment in the systematic notification of deaths occurring after discharge to the hospitals in the Oxford area by a computer method.

Material and Method

Since the beginning of 1962 data from records of every birth, admission to hospital, and death in the population of Oxford and the surrounding area have been abstracted, coded, punched on cards, and matched into personal cumulative files (Acheson, 1964, 1967). This paper deals with hospital discharges and deaths in the defined population during 1963 and 1964. During these years the electromechanical system of data-processing set up in 1962 was replaced by a computer system.

Two cards are punched for each event—an identification card, containing the name, date of birth, N.H.S. number (if known), and other identifying data, and a statistics card carrying coded diagnostic and administrative information. The data are read on to magnetic tape, and edited. They are then sorted into sequence by using the Russell–Soundex phonetic code, sex, and initial as the sorting items, and each new record is compared with all records in the equivalent subdivision of the master file. The system of record linkage is based on the principles described by Newcombe, Kennedy, Axford, and James (1959), whereby discrepant records are dealt with by allotting appropriate weighting factors (positive or negative) to agreements and discrepancies.

The product of the record linkage programme is a compound cumulative file which contains one entry for each person encountered by the system, each consisting of identification data and the records of a variable number of the defined events.

The next step was to scan the master file for all patients whose records included a death certificate and to write these records on to a separate magnetic tape. Records were selected from this tape for patients who had died in 1963 or 1964 and who had been discharged from hospital once or more in that period. An item was then formed for each discharge containing the following data: identification of patient, date of discharge, date of death, diagnosis on discharge (hospital record), and cause of death (death certificate).

If the patient died while in a hospital all items relating to that hospital were deleted, as it was assumed that the hospital was bound to be aware of the death. To avoid multiple notifications of a death where a patient had been discharged more than once from a hospital, the record of the final discharge was the only one retained. By means of the appropriate sorting lists of persons discharged from hospital within the two-year period who died at home or in another hospital were then prepared for each hospital and printed in alphabetical order of surname. Two years after the last death in the series had occurred—that is, at the end of 1966—the lists were sent to the medical records officer of each hospital in the area.

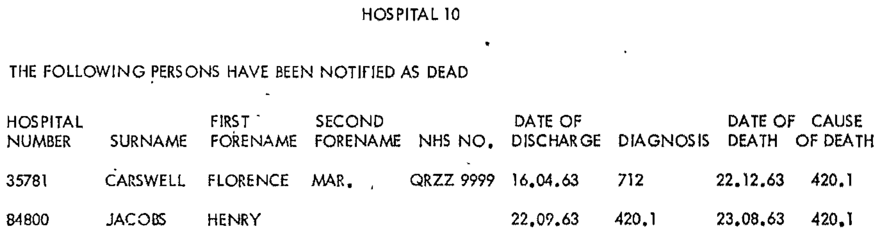
The Oxford Record Linkage Study, Nuffield Department of Clinical Medicine, University of Oxford.

Results

A facsimile of a section of one of the listings is shown in the accompanying Figure, the surnames having been changed to maintain confidence. From left to right are written the names of the patient, the N.H.S. number, the date of the last discharge from the hospital, the code number of the principal diagnosis reached at that time, the date of death, and the code number of the underlying cause of death as stated on the death certificate.



HOSPITAL 10

THE FOLLOWING PERSONS HAVE BEEN NOTIFIED AS DEAD

HOSPITAL NUMBER	SURNAME	FIRST FORENAME	SECOND FORENAME	NHS NO.	DATE OF DISCHARGE	DIAGNOSIS	DATE OF DEATH	CAUSE OF DEATH
35781	CARSWELL	FLORENCE	MAR.	QRZZ 9999	16.04.63	712	22.12.63	420.1
84800	JACOBS	HENRY			22.09.63	420.1	23.08.63	420.1

Facsimile of section of the record.

Table I shows the proportion of deaths about which the various hospitals had been informed before receipt of the listing. Small country hospitals without records departments were excluded from this analysis. Taken overall, a little more than one-third (38.4%) of the deaths had already been notified. The substantially higher proportion of notified cases in the special hospitals (63.4%) was due to the practice at the hospital for chest diseases of searching a complete return of death certificates supplied quarterly by the medical officer of health for the names of old patients. In a previous analysis (Acheson, 1967) it was shown that the proportions of deaths notified were as great in those not dying of cancer as in those dying of this condition—that is, the deficiency was not due to the assumption of death in terminal cases.

In Table II a sample of the cases has been classified according to the time interval elapsing between discharge and death. Though the trend is irregular, the proportion of deaths known to the hospitals falls off as the time interval between discharge and death increases ($\chi^2 = 15.85$; $P<0.01$). Nevertheless, almost half the deaths *occurring within one month of discharge* had gone unrecorded in the records departments of the hospitals concerned.

Discussion

An interesting feature of this study was that it uncovered a deficiency in communication of which the hospitals themselves were unaware. In the two principal groups considerable pains had been taken to ascertain death when it occurred after discharge, both by following up missed outpatient appointments and by scanning the obituary columns of the local papers. The ineffectiveness of these measures came as a surprise. The only hospital with complete information was the chest hospital, which, perhaps because of a long tradition of following up patients with tuberculosis, made a systematic study of the quarterly death returns from the medical officer of health. Another specialist hospital knew of none of the deaths which had occurred after discharge.

Table I.—*Numbers and Proportions of Deaths Occurring After Discharge from Hospital Not Noted in the Hospital Records*

	Deaths Known to Hospital		Deaths Not Known to Hospital		Total
	No.	%	No.	%	
Teaching hospitals ..	362	35·2	677	64·8	1,039
District hospital ..	58	40·0	87	60·0	145
Mental hospitals ..	16	29·6	38	70·4	54
Specialist hospitals ..	90	63·4	52	36·6	142
All hospitals ..	526	38·4	854	62·3	1,380

Table II.—*Effect of the Interval Between Discharge and Death on the Proportion of Deaths Known to the Hospital*

Interval Between Discharge and Death	Death Known to Hospital		Death Not Known to Hospital	Total
	No.	%		
1 month	52	50·0	52	104
2–3 months	71	39·7	108	179
4–6 months	35	26·7	96	131
7–12 months ..	40	40·1	58	98
1 year + ...	10	27·0	27	37
Total ..	208	37·9	341	549

The possible usefulness of feeding back this type of information to hospitals may be considered under three headings—namely, its administrative value ; its value to research workers ; and its possible importance to the clinician in his evaluation of the correctness of the diagnosis, the effectiveness of the treatment, and the accuracy of the prognosis which he had given.

From the administrator's point of view notification of death means that the patient's dossier can be completed and be retired to relatively inexpensive filing space. The risk of importuning the relatives with correspondence addressed to a person who is dead will be avoided. Also, the advantage of accurate notification of death to the clinical research worker is obvious.

It is more difficult to be certain of the value of the data to the clinician himself, and it is proposed to mount a more detailed clinical study of a sample of the deaths with such an evaluation in mind. Preliminary analysis suggests that the majority of the deaths will prove either to have been more or less inevitable or to be irrelevant from the standpoint of the clinician in charge of the final episode of inpatient treatment. However, a minority of the reports are likely to prove of considerable interest in that they may influence the clinician in the treatment of similar cases in future.

If it were thought desirable to provide this type of service on a regular and extended scale, this could be done either by a system of linked records or by asking for the name of the hospital from which the deceased person had been discharged to be recorded on the death certificate. Table II suggests that the service might reasonably be limited to hospitals from which the patient had been discharged within the 12 months before death.

Summary

Only one-third of the deaths occurring within a two-year period after discharge from a group of hospitals had been recorded in the hospital notes of the patients concerned ; of those occurring within one month of discharge from hospital one-half had been recorded. The possible merits of supplying the missing data are discussed from the administrative and clinical points of view.

The Oxford Record Linkage Study is supported by grants from the Nuffield Foundation, the Ministry of Health, and the Nuffield Provincial Hospitals Trust.

Yearly or Quinquennial Grants?

SIR,—Mr. A. McWilliam (19 August, p. 489) gives a general report on the advantages of the quinquennial grant system of financing universities.

It is often implied that this system might be used with advantage in the National Health Service. Comparatively few people, however, have first-hand experience of the application of both the annual and quinquennial systems. The fact that the two methods have existed for 19 years side by side in teaching hospitals and medical schools may be held to indicate that neither system is wholly satisfactory. In this period if one system had no disadvantage it would have displaced the other.

What are the disadvantages of the quinquennial grant system? I think there are none in an economy in which there is no monetary depreciation. The difficulties arise when there is inflation. Mr. McWilliam says, "The quinquennial block grant, without any supplementation except for proved increased costs (and by no means all of these), is both an incentive to economy and a firm basis for forward planning." The unfortunate fact is that, apart from academic salary increases and the rates on property paid to the local authority, there is no significant supplementation throughout the quinquennium. In any recent five-year period rises in wages and non-academic salaries, particularly of technicians, which have not been reimbursed, have severely hampered planned development. Most of the medical schools in London have ended up quinquennia with considerable deficits, which rightly have been carried over as a first charge on subsequent grants.

The development of medical teaching and research is now so rapid and costs rise so unpredictably that five years is too long a period for medical schools or the University Grants Committee to make realistic financial forecasts of recurrent expenditure. The alternative need not be an annual grant, something in between may well be about right.—I am, etc.,

H. B. MAY.

Esher, Surrey.

Disturbed Geriatric Patients

SIR,—We should like to comment on Dr. H. M. Davies's letter (5 August, p. 367). The need for integration of the services for the aged has been recognized by many of those who work in this field. The problem that awaits solution is how to make some progress towards this logical and desirable objective.

Inquiries carried out in this city[1 2] have shown that considerable overlap existed between patients treated in general hospitals, geriatric wards, psychiatric units, and residential homes. Patients requiring medical treatment, psychiatric care, social support, or in need of help in each of these ways were to some extent found in every kind of unit. In an attempt to overcome this a consultant psychiatrist was appointed jointly to the regional hospital board and the local authority in 1961. In 1962 the local authority health and welfare departments combined, and the consultant in geriatrics was given honorary status within the new health and social services department. In 1963 a senior medical officer was appointed by the local authority specifically to assess the needs of the elderly and handicapped referred for and already in residential homes; the liaison so established has been described elsewhere.[3] With this organization a more integrated and co-ordinated service for the elderly has been possible. A more recent development has been the appointment by the regional board of a consultant psychiatrist with special interest in the mental disorders of old age. Psychogeriatric units and day hospitals are being developed in the general and mental hospitals in the city, and it is planned to employ these new developments so as to bring together at regular intervals all those concerned with the care of elderly patients in different settings and thus take further steps towards integration of the services.

The pattern of co-ordinated work that has evolved demands much patience, hard work, and, above all, tolerance and understanding of others' viewpoints, patterns of professional life, and practical difficulties if it is to succeed. Dr. Davies's suggestion to appoint a single doctor to co-ordinate services is a logical objective, but sets up an ideal which at the present stage of development would be difficult to translate into a practical reality. We feel that it would perhaps be better to modify the Newcastle upon Tyne organization, so that joint appointments in both geriatrics (as described by Wollner[4]) and in psychiatry (as in Newcastle upon Tyne) should be made to the regional hospital board and local authority and both consultants brought into a close working relationship with the senior medical officer (geriatrics), who has reciprocal attachments with the regional hospital board. This triad would then be responsible for the integration, co-ordination, and operation of the geriatric services, perhaps along lines already described.[5]—We are, etc.,

Propranolol in Myxoedema

SIR,—May I direct the attention of your readers to a use of propranolol that appears to be insufficiently known?

Patients are not infrequently seen who are suffering from myxoedema, and therefore need treatment with thyroxine, whose hearts are so sensitive to the β-adrenergic enhancement produced by thyroxine that it cannot be used alone. I have seen many myxoedematous patients who develop on very small doses a dangerous tachycardia or angina and a few who have been precipitated into congestive heart failure.

These patients may be restored to health by combining propranolol with thyroxine. They should be treated first with small doses of the former, followed soon by small doses of the latter. The doses of the two drugs are then raised stepwise, any suggestion of cardiac symptoms heralding a slight temporary decrease in the dose of thyroxine and an increase in that of propranolol before the dose of thyroxine is raised again. In this way these patients can eventually tolerate a dose of thyroxine high enough to correct their metabolic deficit.

I am sure that this method of treatment is used by many physicians, but, as the manufacturers of propranolol know of no publication on the subject, I hope that this letter may be useful.—I am, etc.,

Carcinogenicity of Tobacco and Tobacco Smoke

SIR,—I was interested to read (5 August, p. 373) Dr. M. Glass's letter pointing out that cigarette smoker's carcinoma of the finger has never been reported. It is probably not the smoke which seeps through the cigarette paper after the first puff of the cigarette which is dangerous. The very interesting finding that the incidence of bronchogenic carcinoma in those who smoke a given number of cigarettes a day is similar to that in people who smoke half that number but stub out their cigarettes half way through and light them up again later points to the probability that the dangerous part of the cigarette is the part which is raised to a high temperature by the match flame. The carcinogenic factor(s) seem therefore to be contained in the smoke inhaled from the super-heated area. I should like to see an inquiry made into the habits of smokers in order to distinguish those who inhale the first puff of a cigarette from those who reject it before inhaling the subsequent ones.—I am, etc.,

H. DALE BECKETT.

Cane Hill Hospital,
Coulsdon, Surrey.

SIR,—Dr. M. Glass (5 August, p. 373) asks, if tobacco smoke is a carcinogen for man, " Is it not surprising, and indeed significant, that, among the millions of tobacco-stained fingers that have been continually contaminated with tobacco smoke condensates and tars in heavy cigarette smokers . . . not a single instance of cigarette-smoker's finger (papilloma or carcinoma) has ever been seen or reported ? " The shortest answer to this naive question is, " No." Human epidermis is very thick and is protected by a more generous layer of keratin (Figs. 1 and 2) in comparison with the epidermis of the mouse (Fig. 3), which develops cancers very readily in response to the application of tobacco smoke condensates. In terms of thicknesses the epidermis of the mouse and of the epithelium of the human bronchus are not dissimilar.—We are, etc.,

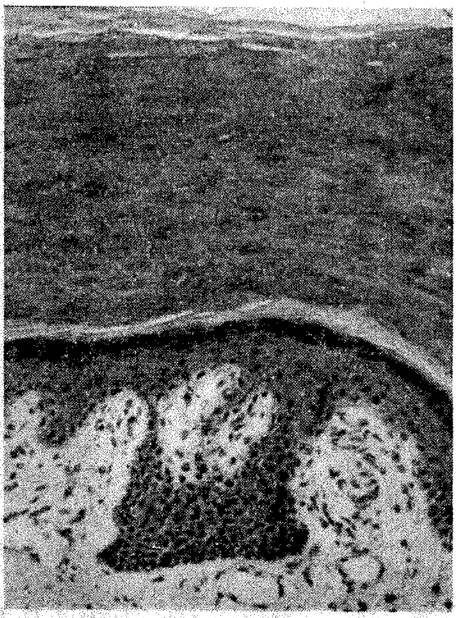

FIG. 2.—Epidermis from palmar surface of human finger. (H. and E. ×180.)

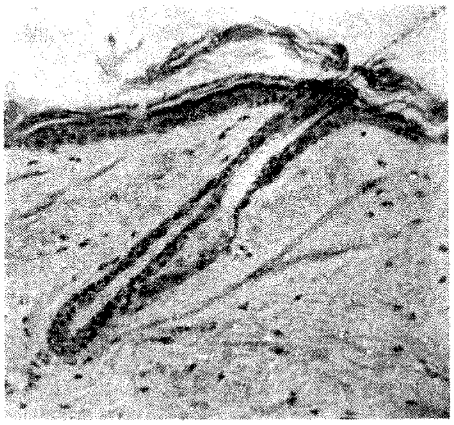

FIG. 3.—Epidermis from dorsal skin of mouse. (H. and E. ×180.)

Carcinogenic Properties of Ortho-dianisidine

SIR,—I do not have any special knowledge of the carcinogenic bases used in laboratories, nor have I done more than discuss with some knowledgeable colleagues the practical problems involved. The following represents the opinion of a chemical pathologist who has used these substances extensively in various analytical procedures during the last 30 years.

Of the dangerous substances few are used in the clinical laboratory. The most important are: (*a*) Benzidine and all its derivatives, including ortho-tolidine and ortho-dianisidine ; (*b*) amino-nitro- and nitroso-naphthalenes, of which the most used are 1-nitroso-2-naphthol for the estimation of urinary 5-hydroxyindole acetic acid, and 1-naphthylethylene diamine, the Bratton and Marshall coupling reagent.

There are a few other reagents incriminated, notably the dyes auramine and magenta, and possibly the nitrophenols ; but these are used relatively little except in the fluorescent staining of tubercle bacilli. Richards and Miller[1] have investigated other fluorochromes, but, as far as I can judge, use for staining would lead to minimal exposure.

Serious danger is due to contamination gross by any analytical standards, such as is unlikely in any clinical laboratory. Reasonable precautions should suffice ; such are the avoidance of pipetting using direct mouth suction, and the use of disposable plastic gloves to handle containers on the outside of which solutions of ortho-tolidine have crept and evaporated. However, we are advised that no threshold dose seems to exist, and, if this is so, it is our moral duty to remove all these carcinogens from routine use as soon as is possible. Fortunately many alternatives are available or will soon become so.

In testing for occult blood benzidine and ortho-tolidine tests have been popular because they are very sensitive and easy to perform. Many observers find their sensitivity too great.[2-4] Indeed, some have concluded that if enough tests were done positive results would occur in every healthy individual. These very sensitive reagents have therefore been modified so that their full sensitivity is not used.[2 5 6] Other less sensitive tests using " safe " reagents, though frequently proposed, are all less convenient ; but in future we shall have to tolerate the inconvenience. Those most popular are the amidopyrin test[7] and the reduced phenolphthalein or phenolphthalein test of Kastle and Meyer, either in its direct form[8] or in the modification described by Varley.[9] The chemoluminescence test of McGrath[10] is inconvenient, though it seems possible that it, alone of the known methods, could be adapted to give an objective reading.

My own experiments with the leuco-bases of green dyes have not produced satisfactory results. I suggest, therefore, that some form of the phenolphthalein test should become standard practice: it is slightly less sensitive than the benzidine test.[11] To avoid the use of ortho-dianisidine or ortho-tolidine in the glucose-oxidase procedures, Trinder[12] has used adrenaline as a chromogen ; his procedure uses nearly twice as much blood as does that of Dick,[13] but even so it is easy to obtain capillary blood in sufficient volume. The Bratton and Marshall reagent can be replaced by a number of phenols ; β-naphthol is possible, and thymol was used in the early days of sulphonamides ; of course such phenols must be coupled in alkaline solution. There appears to be no substitute for 1-nitroso-2-naphthol, but it is possible that a reagent could be prepared extemporaneously, by mixing either an inorganic nitrite with β-naphthol, or hydroxylamine with ortho-naphthoquinone. In this case it could easily be washed down the sink without endangering anyone.—I am, etc.,

Lead Absorption in Children

SIR,—The object of our paper (20 May, p. 480) was to ascertain if, within a certain community, there was any evidence that mentally handicapped children were at greater risk from lead intoxication than children of normal intelligence ; and this we failed to demonstrate. There can be no doubt that it is of the utmost importance to consider lead poisoning when examining children showing evidence of either acute and chronic damage to the nervous system. The co-operation of the Nuffield Department of Occupational Health in carrying out estimations of blood lead levels has made it possible to include this investigation whenever necessary. However, we could not confirm the claim of Sir Alan Moncrieff and his colleagues[1] that the incidence of diagnosed cases of lead poisoning "has risen enormously when the estimation of blood lead becomes freely available." They state that blood lead levels between 40 and 60 µg./100 ml. should be carefully considered in the light of other clinical findings, especially among children under 5 years of age; if levels of over 36 µg./100 ml. of blood are regarded as abnormal, such a finding must raise the question of treatment with chelating agents. At the moment the position seems to be unproved. There is no doubt that everyone in this modern age is exposed to great risks of lead intoxication. Filling the kettle from the hot tap, for instance, can be hazardous.[2] It would therefore be surprising if occasional raised blood lead levels were not demonstrated among the general population. The significance of these in terms of chronic lead poisoning must be further studied.

Sir Alan Moncrieff and his colleagues in their paper did suggest that lead poisoning was commoner among mentally handicapped children than had been realized, and, although they did not say that it was of primary aetiological significance, they stressed that it may add to the brain damage of a child already retarded. In their letter (15 July, p. 174) they state that mentally retarded children with pica are clearly more liable to lead poisoning if there is lead in the environment, and this is true. However, in their paper the 20 mentally handicapped children studied in detail, and treated with chelating agents, did not all have pica. The child with a blood lead level of 48 µg./100 ml. blood was improved after treatment, but may have improved clinically from other factors. There was only a slight change in the assessments on the Griffiths mental development scale before and after treatment, and, depending on the profile, a D.Q. of 43 on this scale at the age of 3 may not be strictly comparable with an I.Q. of 56 on the Stanford–Binet, Form L-M, at the age of 4.

In spite of present legislation in this country there are still many dangers of lead intoxication. Surely much can be done in terms of prevention, and for the protection of children particularly at risk. The treatment of individual children must remain a clinical decision, but an isolated blood level only slightly raised above the accepted level for normal in a particular area would seem an insufficient indication for treatment in the absence of other symptoms and signs supporting the diagnosis of lead poisoning. We are certainly in agreement with the need to know at what level lead becomes actively toxic.—We are, etc.,

Dermatitis from Occlusion Plasters

SIR,—Children who are having one eye occluded as part of the treatment of squint occasionally develop local dermatitis resulting from the plaster. Sometimes, with or without the advice of the family doctor, the occlusion is stopped. This seriously hampers the treatment of a squint, because occlusion should almost invariably be total. There are several other types of plaster available; rarely even these prove to be unacceptable.

There are two types of plaster which can be used in such special cases: Micropore, made by the 3M Co., and Dermicel, made by Johnson & Johnson. Both of these are expensive and cannot be prescribed on an E.C.10; they can, however, be obtained from the hospital. Family doctors should therefore in the circumstances where no other plaster is tolerated insist that the occlusion be continued and advise the mother to obtain a supply of one of these plasters from the hospital forthwith. It is strongly recommended that hospitals should carry stocks of one of these plasters, and should advise parents of squinting children that this type of plaster is available if necessary.

Probably most people are aware of this, but there may be some who are as ignorant as I was.—I am, etc.,

Portsmouth, Hants. NIGEL CRIDLAND.

Experiments on Man

SIR,—The report of the special committee of the Royal College of Physicians on this subject (12 August, p. 429) calls for comment. It is a white-washing, worthless document, purposely vague, and adding nothing to the publicized but often ignored recommendations of the Medical Research Council and the World Health Organization. The R.C.P. not initiating, organizing, or supervising any clinical research, how can its recommendations have any force, and how can they be implemented? What punishments will be meted out to any who flagrantly disregard its recommendations?

The committee divides clinical research into two groups: "the first is that which has direct diagnostic or therapeutic relevance to the individual patient, and which therefore seldom poses serious ethical problems." But it is within this very group that the R.C.P. could have given guidance. The real problem is what constitutes routine investigation. For example, what routine investigations are acceptable for a patient with hypertension? Is either renal biopsy or renal angiography an acceptable routine? What are the acceptable routine investigations in an intensive-care unit? One professor of medicine apparently considers that the insertion of three cardiac catheters into ascending aorta, pulmonary artery, and right atrium respectively to be a justifiable routine in such a unit. Would the committee agree?

The problem can be discussed another way. What are the indications for various investigations—for example, liver puncture, coronary angiography, combined right- and left-heart catheterization, renal angiography, etc.? Does not the committee realize that much questionable research is done under the guise of routine investigation? Does the committee seriously advise, as they appear to do in the report, that a doctor "could sometimes be said to have failed in his duty" if he did not perform any one of the investigations listed above? I wonder how many of the committee have actually read my book *Human Guinea Pigs*.[1]

We are informed: "even the most experienced workers would often welcome the opinion and advice of their peers." The words "peers" was no doubt carefully chosen as the most apt for an R.C.P. report. But who are the peers from whom the various professors, who are primarily research workers, are likely to seek advice?

I agree that the board of governors "has a responsibility to ensure that all clinical investigations carried out within its hospital or institution are ethical. . . ." But do the governors know of and understand the clinical research going on in their hospital?—I am, etc.,

Digital Ischaemia and Malignant Disease

SIR,—I was interested to see the article by Mr. P. R. Hawley and colleagues (22 July, p. 208). The following case adds a further diagnosis to the association between digital ischaemia and malignant disease.

A 51-year-old quantity surveyor was seen in hospital on 25 September 1961. He gave a history of pain, blanching, and coldness of the left middle finger starting about the beginning of August 1961. On examination he was found to have incipient gangrene of the tip of the left middle finger. On 23 February 1962 the top of the left middle finger came off spontaneously and the pain was subsequently relieved.

Shortly afterwards, however, he felt unwell. He reported at outpatients on 30 April 1962, complaining of diarrhoea, sore throat, and loss of weight of 1 stone. On examination he was found to have generalized tender lymphadenopathy and the liver and spleen were just palpable. He was admitted to hospital, and a biopsy of glands from the groin and axilla showed a reticulosarcoma with total loss of normal lymph node architecture and replacement by sheets of pleomorphic cells and giant cells; there was increase in coarse reticulin. He died on 23 June 1962.

Post-mortem examination showed reticulum-celled sarcoma involving widespread lymph nodes, liver, kidneys, and gastric, intestinal and vesical mucosae. Death was ultimately due to bronchopneumonia.

This case would support Hawley *et al.* in their premise that unexplained, spontaneous digital ischaemia, particularly in those over 50, warrants very thorough investigation to exclude a malignant condition.—I am, etc.,

Dorchester,
Dorset. EDWARD JARRETT.

Safer Dental Anaesthesia

SIR,—Intravenous anaesthesia represents for the patient nothing less than a revolution in dental treatment and is one of the greatest advances in dentistry of modern times. But is it safe? This is an all-important question that must be answered.

The present death rate from dental anaesthesia, all methods included, is stated in a recent leading article comment in the *British Medical Journal*[1] to be at about four to six a year in this country, a marked improvement on the not-so-distant past. In 1952 22 lives were lost. Similar comment in the *Lancet*[2] puts the yearly total of administrations for extraction of teeth in the National Health Service at 1.7 million; to which, it says, must be added a large number given in private practice for this purpose, and an increasing number given for conservative dental work. It thus appears that in present-day practice the risk incurred in dentistry by the use of a general anaesthetic is exceedingly small. And most of these deaths occur in patients anaesthetized in hospitals, the mortality in dentists' surgeries being about one in a million.[3] Unfortunately, there are no figures to show to what extent, if any, the intravenous method is contributing to this mortality. My own views on this question[4] were based on an analysis of 37 deaths about which I had collected such information as there was; and on more than 100 cases, described to me by the dentists in whose surgeries they had occurred, of patients who came to the very brink of death but survived. I concluded that it made little difference what anaesthetic was used or who gave it; the problem was the traditional upright position of the patient, and the only effective remedy was to abandon that position.

At a recent demonstration I attended the patient took her place in the chair, which was promptly lowered into the horizontal position, forming in effect a level couch. The dentist gave an initial injection of anaesthetic intravenously, leaving the needle in situ, and then seated himself at the head of the patient. On either side of him sat his nurse assistants. The patient's colour was a healthy pink, her breathing was free and rhythmical, and she had all the appearances of being quietly asleep. A mouth pack was carefully placed in position, the nurse on the dentist's left directed the suction nozzle to the site of operation, and work began. At intervals of about two minutes further small increments of anaesthetic were given by one of the nurses until, about 12 minutes after the start, the dentist had finished. Two minutes later the patient was awake. At no time had any help been needed with the airway, and the dentist had been able to proceed with his work untroubled and without interruption. About 20 patients were treated in similar fashion.

The smoothness of the whole performance raised the query of what is the role of the second practitioner whose presence is strongly advocated by many people. Complications are rare, and, with the patient in the supine position, they present little difficulty, either in recognition, diagnosis, or treatment. There are three of major importance: obstructed airway, laryngeal spasm, and vomiting; and the persons best placed to spot them at once and deal with them effectively are the dentist and his nurses, poised, as they are, straight over the patient's face. The second practitioner's function could be to assess the patient's fitness for anaesthesia. There would be some point in this if he is required to be medically qualified, but this is not stipulated by those who insist on his presence.

What then can be the role of the second practitioner? I believe it is this: to help dentists who are unable to give the anaesthetic themselves. Anaesthesia is a demanding responsibility and training for the dual role is hard and expensive. The standards required are the highest attainable. And it is in fact to safeguard these standards that the Society for the Advancement of Anaesthesia in Dentistry has long desired teaching to be placed on an official basis, under the aegis of the Faculty of Anaesthetists, with a diploma for successful candidates. There is therefore plenty of room for the second practitioner; and dentists and doctors (and perhaps others, as I have suggested in a recent publication[5]) should be trained for this work.

The intravenous method is, I believe, inherently safe for the dentist who wishes to give his own anaesthetics, with certain provisos. Firstly, the dental work for which the anaesthetic is given must not be unduly prolonged, and require no more than the lightest levels of unconsciousness; secondly, the dentist must have been properly trained in the use of the intravenous method; thirdly, he must employ at least two nurses of suitable status and training to assist him; fourthly, his patients must be recumbent; and, finally, he must use always the smallest amounts of anaesthetic that meet the requirements. With such doses the patient is never more than two minutes from being virtually awake.—I am, etc.,

Salisbury,
Wilts.

[5] —— *Studies in Anaesthetics: Including Intravenous Dental Anaesthesia*, 1967, p. 159. London.

SIR,—Your correspondent Mr. S. L. Drummond-Jackson (12 August, p. 436) condemns the Government Report on Dental Anaesthesia[1] on the grounds that it lacks "conciseness and clarity" to such an extent that the British Dental Association has mistakenly expressed agreement with two important points made in the report, with which Mr. Drummond-Jackson feels they could not possibly have agreed had the report made its real meaning clear.

The first of these points is contained in paragraph 31 of the report, and this paragraph Mr. Drummond-Jackson interprets as implying that "dental students should receive no practical training in anaesthetics." Paragraph 31 contains the following sentence: "It seems to us that undergraduate instruction, including any clinical practice, should concentrate at an elementary level on the principles of anaesthesia, on the pharmacology of the drugs used and the risks inherent in their administration, on the basic conditions for safety, and on resuscitation." It is difficult to see why the British Dental Association should find this recommendation neither concise nor clear, and it is even more difficult to see why Mr. Drummond-Jackson should interpret the phrase "including any clinical practice" as meaning that no practical training should be given. The recommendation seems concise and clear enough to me. Furthermore, in a recent conference on general anaesthesia in dentistry called by the British Dental Association the following exchange is recorded.[2]

"Dr. Coplans asked if undergraduates entered any of the classifications or were they to be taught nothing at all? Dr. Bourne replied 'theory only.'"

Mr. Drummond-Jackson, who was sitting opposite me at this conference, raised neither an eyebrow nor any objection to this reply; no more did any of the five British Dental Association Representatives present, and indeed there was absolute agreement expressed by all parties represented that undergraduate training no longer fitted a doctor or dentist to administer anaesthetics routinely, nor should it attempt to do so—a view at least as extreme as any suggested by the report itself.

The second point is said to be contained in paragraphs 33, 34, and 35 of the report, which Mr. Drummond-Jackson interprets as implying that "dental graduates could not receive any postgraduate training which would enable them to provide a service." In fact the paragraphs in question simply suggest a number of different forms of postgraduate course designed to meet different needs, the details of which the report quite rightly leaves open for further discussion between the relevant medical and dental bodies. In the first of these discussions, the conference already referred to, the only positively restrictive idea emanated surprisingly enough from Mr. Drummond-Jackson himself, who suggested that in the future "the only man who could give dental anaesthetics was the man who attended such and such a course." [2]

Let us hope that the British Dental Association's agreement with large and important sections of the report will continue on the basis of the report's actual content, rather than be destroyed by careless misinterpretations of its main recommendations.—I am, etc.,

Holiday Camps for the Disabled

SIR,—This is a plea for careful medical examination of any disabled who are recommended even for a short holiday at a camp for disabled. The benefits of such a holiday are obviously great for disabled persons and also for relatives who may have to look after them for the rest of the year.

A good example of this was one cripple, unable to get about except in a wheel chair, who had been entirely dependent on and never left his mother's care for 40 years. After a holiday at one of our camps his whole personality changed; he took to going about by himself, learnt to type, and became secretary of the local disabled club. Imagine the relief for his mother.

But it is only fair to ask that cases should be selected with care and with a knowledge of the conditions at a particular camp and of the voluntary personnel available to look after them there.

The camps are made available to the Red Cross at much reduced rates by the generosity of the owners and by the unstinted personal generosity of camp managers and camp staff, who often freely give of their own holiday periods or own off duty hours to help these disabled. The personnel of the voluntary organizations who undertake these holiday duties, although fully trained to the highest Red Cross and St. John nursing standards, are not professionally qualified nurses and may have had little hospital nursing experience; the personnel, women and men, are often in full-time employment, in shops, offices, or homes, and only able to give part-time help in their spare time or even in their own holiday periods. We have several men who give 7–10 days of their own annual fortnight's leave period to help with this.

We make a point of always having at least one or two fully qualified nurses on the roster of duties, but it is only fair that all cases should be carefully selected, and disabled who require heavy continuous hospital care and attention should not be recommended for a holiday at one of the camps for the disabled.

Having been associated for nearly 20 years with the holiday camps for disabled my plea is that those who are asked to examine and recommend any disabled for a holiday should realize the conditions involved.—I am, etc.,

Mental Illness in Foreign Nationals

Sir,—There have been many studies in Britain on immigrant populations,[1-3] but the amount of mental illness among them is uncertain. This preliminary report draws attention to some of the features of mental illness as seen in this hospital.

During recent years the number of foreign national patients admitted here has increased (geographical distribution is shown in Table I and diagnosis in Table III). These patients were treated and in the main discharged to their relatives or homes in Britain within a few weeks or months. However, a number have remained in hospital, and it seems probable that this number will increase. In March 1966 there were 135 long-stay patients of foreign nationality in Banstead Hospital, of whom 21 probably could be rehabilitated. The rest even with only residual psychotic symptoms proved resistant to rehabilitation because of, among other things, a formidable language barrier and lack of relatives or friends.

Table I.—*Foreign National Admissions During* 1966

	Male	Female
European	23 (Poland 12)	7 (Poland 8, Spain/ Portugal 9)
Asiatic	17 (India/ Pakistan 11)	8 (Ceylon/ India 4)
Western Hemisphere	19 (West Indies 11)	2 (West Indies 10)
African	16 (Nigeria 7)	2 (Nigeria 6)
Australasian	4	8
Eire	42	9

Table II.—*Foreign National Inpatients in March* 1967

	Male		Female	
	Short-stay*	Long-stay†	Short-stay	Long-stay
European	7	52 (Poland 33)	5	22 (Poland 7)
Asiatic	1	5	3	3
Western Hemisphere	4	3	2	0
African	1	1	2	0
Australasian	0	1	1	0
Eire	5	10	3	3

* Less than six months. † More than six months.

Table III.—*Diagnoses in* 115 *Foreign Nationals in Hospital*

Diagnosis	Male		Female	
	Short-stay	Long-stay	Short-stay	Long-stay
Paranoid Schizophrenia ..	4	29	2	12
Schizophrenia (unspecified) ..	4	24	8	9
Organic	2	7	1	4
Affective disorders and others ..	5	1	2	1

Table IV.—*Repatriation in Longstay Patients*

	Male	Female
Definite wishes not to return to country of origin	8	8
Vaguer wishes/changeable/ psychotic	11	2
Unknown	43	16
Definite wish to return ..	8	1

There are other difficulties peculiar to these patients. Correspondence with their embassies is often protracted with long delays; sometimes relatives deliberately try to prevent the patient returning home; occasionally the patient is reluctant to return to his country because his judgement is poor and he may be quite unrealistic about his ability to adjust to life in this country. Two case histories illustrate some of these points.

Case 1.—The patient was born in Freetown, Sierra Leone, and is aged 34. He came to Britain in 1960 to study medicine. He failed his first M.B. three times in all subjects, had to leave, and drifted to London, where he has failed to adjust to any work or life in general. He has had a number of mental hospital admissions and some minor difficulties with the police—for example, failing to pay his fare on the train. He expresses a number of simple wish-fulfilling delusions. For example, when he travels he feels he need not pay because he is related to the Royal Family; at times he believes he is a prince of one country, while at times a prince of another quite distinct country. He is in fact a well-preserved young African, well-spoken, in touch with his surroundings, if rather aloof and solitary.

This illness would seem to be related to his inability to adjust to any way of life in England because he has no family here nor any real prospects.

Case 2.—The patient was born in Poland and is aged 46. He came to Britain with the Polish Forces in 1946, and following his discharge from the Army worked as a labourer intermittently until he was admitted to Banstead Hospital in 1951 with paranoid schizophrenia. He has had the usual range of treatment and remains on his optimum dose of phenothiazines. He believes he is being persecuted by the Communists, and so in spite of repeated requests by his father in Poland for his son's repatriation the patient refuses to consider it. In spite of the residual delusions he has been rehabilitated as far as working outside the hospital for the last five years, but resists any efforts to help him live outside. He is physically fit, has an adequate command of English, but is settled within the hospital and seems content as things are.

We have a large number of Poles who, in the main, became ill within a few months or years of coming to this country after the last war (Table II). Obviously for them repatriation is now hardly a possibility. Patients' views on repatriation are shown in Table IV. Psychiatric patients have a specific disability in adjusting to their environment, as distinct from patients who are physically ill. It is generally agreed that foreign culture is itself a stress and may make readjustment after psychiatric illness more difficult. For this reason it is to be expected that the long-stay chronic schizophrenic population could well increase with the years ahead.—I am, etc.,

"Swallowed" Endotracheal Tube

Sir,—Following the recent article on "swallowed" endotracheal tubes in neonates by Mr. J. A. S. Dickson and Mr. G. C. Fraser (24 June, p. 811), and the further report by Mr. M. G. Prinn (15 July, p. 176), I would like to report a similar case.

A mother was admitted to the Nuffield Maternity Department, Oxford, with severe pre-eclamptic toxaemia at 37 weeks and had a low forceps delivery of a male infant weighing 5 lb. 8½ oz. (2.5 kg.). Endotracheal intubation with a Portsmouth tube proved necessary, but momentary relaxation of the hold on the tube caused it to become gripped by oesophageal peristalsis and lost. The infant was admitted to the special care baby unit in good condition, respirations were slightly grunting, and rather frequent mucus extraction was required. A plain *x*-ray was unhelpful owing to the radiolucency of the tube. An oesophagoscope was passed without anaesthetic by Mr. A. J. Gunning, who found the tube lying just below the cricopharyngeus, from where it was easily removed. The infant's subsequent progress was uneventful.

It would be a great advantage if the tubes could be made opaque to *x*-rays by the inclusion of a radio-opaque salt, as is done already in the case of the Liverpool Holter valve tube.[1]—I am, etc.,

What is Psychosomatic Disease?

Sir,—Dr. J. W. Todd's letter (5 August, p. 368) following the paper by Dr. F. Feldman *et al.* and your leading article (1 July, pp. 14 and 1) resurrects a semantic misconception which some of us have laboured long, and we might have hoped fruitfully, to resolve. The adjective psychosomatic is properly used to describe either an approach to clinical medicine or research, or the mechanism whereby certain reactions occur in patients. Since the vast majority of human beings are conscious and react through their autonomic and neuroendocrine systems to their experience and their environment, all disorders of health are to some extent properly regarded as containing a psychosomatic element. To disregard this is to equate medicine with mechanics; an even older historical blunder than that adduced in Dr. Todd's telling examples.

The basically indisputable case for including a psychosomatic appreciation in the clinical approach to any illness has been painstakingly elaborated in innumerable publications, and is succinctly summarized in terms which leave no room for doubt in two reviews of the subject included in a recent textbook and the revised edition of an original paperback.[1] [2]—I am, etc.,

[2] —— *Psychiatry Today*, 2nd edition, pp. 239 to 242. Pelican Books.

SIR,—Dr. John W. Todd (5 August, p. 368) claims that the use of the term psychosomatic can be justified only if a disease is invariable—and he quoted a *B.M.J.* leading article: "an illness in which the organic lesions are the consequence of emotional disturbances." This is, I agree, the sense in which the term is most commonly used by doctors. But surely, where the organic lesions are the consequence of emotional disturbances, the correct description is "psychogenic"?

Psychosomatic has in fact a wider connotation; it embraces those disorders where mind and body interact to cause symptoms. For example, Kissen[1] was able to show that a break, or a serious threat of break, in a romance, engagement, or marriage was significantly often associated with the onset of tuberculosis. Nobody in his senses would argue, from that evidence, that the break *caused* tuberculosis. But if, say, a broken romance weakens resistance, in some way, to tuberculosis, then tuberculosis is to that extent psychosomatic.—I am, etc.,

Court Lees School

SIR,—Three matters about this disturbing case puzzle me. Firstly, did the pathologists have no opportunity to make a clinical examination of the boys? Secondly, was there an adequate check of the accuracy of the colour reproduction in the photographs? Thirdly, was an examination made to establish the date on which all bruising had disappeared?

Perhaps the pathologists can reassure your readers on these points.—I am, etc.,

J. H. LANKESTER.

Oxted, Surrey.

Coroners' Jurisdiction

SIR,—Mr. H. A. Kidd (5 August, p. 372) contends that there was a failure to consult the Central Consultants and Specialists Committee before the submission of evidence to the Brodrick Committee and also that the members of the Association were given no opportunity "of deciding whether they would continue to support the present system of coroners' jurisdiction or would prefer a system similar to the procurator fiscal in Scotland." These contentions are false, as the following account of the sequence of events shows.

"Deaths in the Community" was produced in 1963, and was fully discussed by all the interested Committees, including the Central Consultants and Specialists Committee and the G.M.S. Committee, before being accepted by the Council. Indeed, detailed comments prepared by the Medico-Legal Subcommittee of the Central Consultants and Specialists Committee were considered by the Private Practice Committee on 10 April 1963, prior to the submission of the final document to the Council. The report, which deals very fully with the defects of the procurator fiscal system, was included as an appendix to the Annual Report of Council in 1963, when, on a specific Motion, it received the approval of the Representative Body and thus became Association policy. The unaltered, published report was submitted to the Brodrick Committee in 1964 as the Association's written evidence.

In May 1965 the Brodrick Committee invited the Association to reply to a questionary. This task was remitted to the Private Practice Committee, which referred the matter to its Forensic Medicine Subcommittee. The Central Consultants and Specialists Committee and the G.M.S. Committee were again consulted and, so far as the Central Consultants and Specialists Committee is concerned, replies to the questionary drafted by its Medico-Legal Subcommittee were incorporated in the replies finally sent on behalf of the Association with the approval of the Council. In fact, before the replies were finalized the Forensic Medicine Subcommittee had considered a memorandum prepared by Mr. Kidd and forwarded by the Central Consultants and Specialists Committee. It was decided that Mr. Kidd's paper produced no additional points which ought to be forwarded to the Brodrick Committee on behalf of the Association. No dissentient voice was raised in the Council on behalf of the Central Consultants and Specialists Committee.

There followed a long interval of time before the Association was invited to give oral evidence to the Brodrick Committee. Meanwhile, in May 1966, a further memorandum was received from the Central Consultants and Specialists Committee, prepared by Mr. Kidd, and considered by the Executive Subcommittee of the Central Consultants and Specialists Committee on 25 April 1966. This memorandum differed slightly from the one which had been rejected in 1965, and in submitting it the Executive Subcommittee asked if the Forensic Medicine Subcommittee would give Mr. Kidd an opportunity of attending personally and speaking to his paper. On 10 January 1967 Mr. Kidd duly attended a meeting of the Forensic Medicine Subcommittee, which decided that it could not support his views. This action was subsequently approved by the Private Practice Committee and on 1 February 1967 by the Council, prior to the attendance of the Association's representatives before the Brodrick Committee. All the relevant facts were brought out during the debate in Council on 1 February 1967, when an earlier request from the Central Consultants and Specialists Committee that some support should be given to Mr. Kidd's views was withdrawn. During this debate I agreed, at the request of Dr. Skene, to invite one consultant engaged in clinical medicine or surgery to join the deputation to the Brodrick Committee. The Council approved my statement that this could only be done on the understanding that there would be no departure from the general tenor of the evidence which had already been submitted. To have done otherwise would have been unfaithful to the Representative Body.

In light of these facts, I am surprised to see Mr. Kidd's statement that the Central Consultants and Specialists Committee subsequently sent his rejected memorandum to the Brodrick Committee. If the statement is true, I must question the propriety of such action.—I am, etc.,

IVOR M. JONES,
Chairman,
Private Practice Committee, B.M.A.
Chairman,
Forensic Medicine Subcommittee.

"Long-acting" Corticotrophin

SIR,—We are interested to see Dr. M. Friedman's study using plasma 11-hydroxycorticosteroid levels to measure the relative activities of two long-acting A.C.T.H. preparations (12 August, p. 409). Undoubtedly this study demonstrates that the duration of the increase in plasma 11-OHCS levels in response to A.C.T.H. gelatin is greater than that seen with the same dose of A.C.T.H./c.m.c. used in this experiment by a difference which is small but significant.

Gelatin is added to A.C.T.H. to delay its release and to prevent its breakdown at the site of injection. The clinical duration of activity of a long-acting A.C.T.H. preparation may range from less than 24 hours to more than 72 hours; this has been borne out in clinical practice with A.C.T.H./c.m.c.[1] It is not our intention to develop an A.C.T.H. preparation which lasts exactly as long or longer than any of the A.C.T.H. preparations already available. We are as yet uncertain of what significance can be placed on the exact duration of elevation of 11-OHCS or plasma cortisol following A.C.T.H. and how this ties up with the results seen in clinical practice.

The Mattingly method[2] of plasma 11-OHCS estimation is recognized as a good and useful indication of changes in plasma levels of a certain fluorescing fraction largely comprising cortisol, but should perhaps not be used as an accurate means of comparing response to different A.C.T.H. preparations when one does not know what proportion of the fluorescent response is due to cortisol and what proportion is due to other factors. It has been shown that 27–55% of the fluorescence obtained during the Mattingly procedure may in fact be due to substances other than cortisol.[3] When one measures the plasma 11-OHCS levels it would be useful to know exactly what is being measured and to be able to correlate these figures with clinical activity.

We are as yet not aware of how long the ideal prolongated preparation should act. Each individual patient varies in his requirements, perhaps owing to differences in rate and degree of inactivation of the A.C.T.H. injection, cortisol turnover rate and distribution, and the disease process involved. Clinical observations of therapeutic effects and side-effects are of more use in practical A.C.T.H.

therapy than biochemical estimations alone. We would therefore respectfully suggest that before reaching a conclusion on Dr. Friedman's study with regard to clinical activity one must first correlate this latter with the plasma 11-OHCS curves described. We would, however, repeat that we have no desire to produce a long-acting A.C.T.H. preparation which has an identical duration of action to any other prolonged A.C.T.H. at present available.

We would maintain that A.C.T.H./c.m.c. represents a highly purified long-acting A.C.T.H. preparation with a therapeutic action which is similar to A.C.T.H. gelatin and every other natural A.C.T.H. preparation, but which has two additional practical advantages—the first is its liquid nature and the second is its stability. These properties facilitate subcutaneous injection and make self-administration a more practical form of A.C.T.H. therapy for the outpatient. The necessity of warming a heat labile compound before administration is avoided.—I am, etc.,

Disinfectants and Plastic Mop Heads

SIR,—We have read with interest the letter from Dr. D. A. Leigh and Miss Christine Whittaker (12 August, p. 435) on the interference with the disinfectant property of Hycolin and Roccal by plastic mop heads. They found much less interference with Sudol, and recommend that this disinfectant be used with these mops. Adsorption of quarternary ammonium compounds, such as Roccal, by plastics (and many other materials) is well known. Such an occurrence in respect of phenolic disinfectants is less well known.

Our own observations in this connexion may be of interest, since they extend those reported by Dr. Leigh and Miss Whittaker. Using the same plastic sponge (which the manufacturers of this mop inform us is composed of polyvinyl acetate) we have found that both Hycolin and Sudol disappear from solutions in which it is immersed. In the case of Hycolin, using just sufficient of a 1 in 20 dilution to cover the sponge on all sides, rather more than 75% of the disinfectant disappears from the solution in 24 hours. With Sudol about 50% so disappears. Replacing the disinfectants with fresh solutions daily, we have found that the rate of disappearance slows down, and ceases in the case of Hycolin after eight days, but can still be shown to occur with Sudol after 40 days.

Both Hycolin and Sudol can be recovered from treated sponge for a considerable time. This recovery continues even when the sponges are washed out thoroughly under a running tap daily before being immersed in water to test for elution of disinfectant. In the case of Hycolin recovery continued for eight consecutive days under such circumstances. With Sudol recovery continued for at least 10 days. It seems likely, therefore, that the disappearance of these substances from solution can be entirely explained by this adsorption by the sponge.

We observed that Sudol makes the sponge material soft and "mushy" after prolonged immersion. Contrary to the suggestion made by Dr. Leigh and Miss Whittaker, we feel, therefore, that Hycolin is more suitable for the disinfection of this mop head, particularly since within a few days it becomes saturated with the disinfectant, and the adsorbed disinfectant appears to retain its bactericidal activity. Our work is being continued, and we hope to publish it in full, with technical details, at a later date.—We are, etc.,

Opportunities in British Medicine

SIR,—Having read the leading article entitled "But eastward, look, the land is bright" (15 July, p. 128), I viewed with considerable concern the presidential address delivered at the 135th Annual Meeting at Bristol, entitled "One Profession, One Purpose" (15 July, p. 129). The repetition of numerous platitudes in a situation in which the practice of medicine no longer remains attractive to the younger graduate in Britain will not in any way prevent the ever-increasing flood of emigration to a more free system of practice. The comments with regard to loans and "an enforced period of service," whether this be in Egypt or in the United Kingdom, are typical of the lack of constructive thinking by the establishment on how to prevent emigration. The obvious answer is to improve conditions of practice and to offer an attractive career in a free profession.

The Minister of Health has made it clear that he will not allow an expansion of private practice at the present time, as this will cause a further decrease in the standards of National Health practice. The interpretation is that a universal steadily deteriorating standard of medicine will continue in Britain.

As always, the issues have been, and remain, crystal clear. Medical men are as anxious as politicians to ensure that no financial barrier should deter the sick person from consulting the physician. The duty of the doctor, whether general practitioner or specialist, is prevention and treatment of illness, and a private system of contracting between patient and doctor is the most satisfactory method of ensuring rewards for diligence, efficiency, further training, ability, or a manner which inspires confidence. The duty of Government is to reimburse the patient according to individual need, and for this the politician must answer to the electorate. These two matters are entirely separate, and unfortunately the leaders of the British medical profession are aiding and abetting successive Governments in confusing for political ends the profession and the public. From this side of the Atlantic the prospects of the young doctor in Britain remain apalling, as the basic issues are as yet untackled.

In a hospital in which approximately 50% of the specialist staff are from Britain, my colleagues and I feel it our bounden duty to advise and encourage our younger colleagues to emigrate from the United Kingdom. On this Continent the leaders of the profession are determined to preserve a fee-per-item-of-service basis of remuneration, contracted privately between the individual doctor and the patient, and we look forward to increasing the medical personnel with more graduates from the United Kingdom, whose value to the community will be suitably rewarded.—I am, etc.,

J. W. DAVIDSON.

Toronto,
Canada.

Impression of General Practice

SIR,—In this group practice we are becoming increasingly concerned and alarmed at the present image of general practice and community medicine that exists in the minds of medical students.

Undergraduates come to our practice for training from one provincial and two London medical schools. Virtually none of them is considering general practice as a career, although the majority have not decided on a specialty. They appear to have formed the impression, without any first-hand knowledge, that proper medicine is done purely within the confines of a hospital, and that general practice is for failed specialists.

The situation might be described as farcical, were it not for the fact that general practice needs a considerable increase in recruits over the next few years. Until these false impressions are corrected in the minds of tomorrow's doctors the increase will not come. Many general practitioners are anxious to widen their undergraduate teaching programme considerably. The medical schools, however, do not seem to encourage their students, nor do the educational planners appear to sense the urgency of remedying this unfortunate attitude, both in the minds of the students and in those of some of their clinical teachers.—We are, etc.,

Points from Letters

Psychological Factors and Ulcerative Colitis

Dr. IAIN DUNCAN (Annan, Dumfries-shire) writes: It is interesting that Dr. H. Gainsborough's salutary reminder (19 August, p. 499) of the importance of understanding the patient fully, in all the ramifications of his personal being, is given in relation to ulcerative colitis. However, it applies cogently to two other subjects in the same columns—namely, asthma and enuresis, and indeed to every disease with which we deal. A general practitioner in particular is privileged to have the opportunity of really knowing the patient as a person, since he has contact with him in a variety of situations and relationships, and sees him against the background of his work, his community contacts, and in the exposed intimacy of the very home where he performs the fundamental process of existence. As Dr. Gainsborough says, evidence based on this kind of observation is subjective but none the less valid and should not be discounted just because we do not measure it in terms of absolute values.

Obituary Notices

GREGORY PINCUS, D.SC.

Dr. G. Pincus, the eminent biologist best known for his work in developing the contraceptive pill, died in a Boston hospital on 22 August. He was 64.

Gregory Pincus was born on 9 April 1903 at Woodbine, in New Jersey, U.S.A. He studied firstly at Cornell University, where he took a bachelor's degree in science, and then at Harvard, where he gained successively a mastership and a doctorate of science. He travelled to Europe, first to the Kaiser Wilhelm Institute in Berlin, and came to England in 1930 to study at Cambridge. He went back to the United States a year later, and became successively lecturer and assistant professor in the department of biology at Harvard. He returned to Cambridge in 1937, where he was a visiting investigator, after which he held posts at Clark University and Tufts Medical School in the United States, and was finally appointed research professor of biology in Boston in 1951, a post he held until his death.

[Keystone Press Agency, Ltd.

His interest in the biology of reproduction was manifest as early as 1936, when he published *The Eggs of Mammals*. His interest became more and more focused on the role of the steroid hormones. With the introduction of orally active synthetic progesterone in the early 1950s Dr. Pincus saw the possibility of using this as an oral contraceptive agent. With colleagues at the Worcester Foundation for Experimental Biology, Shrewsbury, Massachusetts, where he was research director, he tested the inhibitory activity of a large number of compounds. Having narrowed his choice to a selected few, he, together with Dr. John Rock, began clinical trials on Puerto Rican women.

Their remarkable results were published three years later and established the contraceptive pill as far superior to any other method of contraception currently in use. His interest in reproductive physiology continued, and he made a number of important contributions to the literature on this subject.

Many honours were bestowed upon him. In 1957 he received the Oliver Bird Prize for his contributions to the study of fertility control, and the Lasker Award for Planned Parenthood was bestowed upon him in 1960. The University of Edinburgh awarded him the Cameron Prize in 1966. He was elected fellow of many scientific societies in the United States, South America, Japan, and Europe.

He is survived by his wife, a son, and a daughter.

A. K. writes: Gregory Pincus has to his credit three great accomplishments, any one of which would have fulfilled the life of a lesser man. He was the chief creator of the Worcester Foundation for Experimental Biology, which from a very modest beginning grew to be a Mecca for endocrinologists from all over the world. The Laurentian Hormone Conference was his brain child and he edited the yearly volume of *Recent Progress in Hormone Research* that came from it. To be asked to give a paper at the Laurentian is the highest accolade in the endocrinological world, and the standards set by Gregory Pincus made it so. No man in science now stands alone, and Gregory Pincus would be the first to acknowledge that others have a share in the development of oral contraceptives, but to him rightly belongs the main credit for the invention that has touched closely the fabric of society in the Western world and goes far to meet one of the most pressing problems of our times.

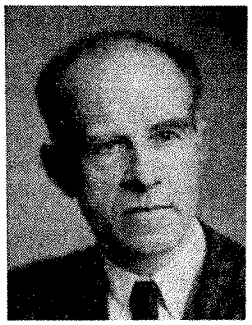
Gregory Pincus had in abundant measure the American gift for informality, but his relaxed air went with a formidable professionalism. Under his guidance it was always shirt sleeves and christian names at the Laurentian, but the arrangements ran with a smoothness which was no accident, and *Recent Progress in Hormone Research* appeared on time every year and with the references correct. He had a sardonic humour which was a perfect foil for the Russian ebullience of his wife Liz. They kept open-house in Shrewsbury, and many British endocrinologists have enjoyed the hospitality of their beautiful home.

Although Gregory and his friends all knew he had not long to live, he did not desist from starting new ventures. Negotiations for an academic connexion for the Foundation were in hand, and a few days before his death letters went out to endocrinologists all over the world arranging for the foundation of an international society for the study of reproductive physiology, the project long close to his heart. Medicine owes much to this man who was not medically qualified, and British endocrinologists grieve for the loss of a great master and a stout friend.

E. B. VERNEY, M.A., M.D., F.R.C.P., F.R.S.

Professor E. B. Verney, emeritus professor of pharmacology in the University of Cambridge, died on 19 August after a short illness.

Ernest Basil Verney was born on 22 August 1894, and after attending Tonbridge School entered Downing College, Cambridge, as a scholar. There he obtained a first-class in the Natural Sciences Tripos, and qualified with the Conjoint diploma at St. Bartholomew's Hospital in 1918. He graduated M.B., B.Ch. in 1921. He spent two years in the R.A.M.C., and after the usual house posts became an assistant in physiology at University College and later an assistant in the medical unit at University College Hospital. It was at this period that he worked with E. H. Starling on the systematic study of cardiovascular control that the flexibility of the heart-lung preparation made possible. It was immediately evident that Verney had gifts of a quite exceptional order as an experimental physiologist, and he soon achieved wide recognition. In 1926, when the chair of pharmacology at University College fell vacant, he was elected to it, and during the subsequent years his interests gradually shifted to the control of urinary secretion, at first using methods similar to those previously used in his study of the circulation. In 1934 he was invited to succeed Walter Dixon as Sheild Reader in Pharmacology at Cambridge, and he was also elected a fellow of his old college, Downing. He became the first Sheild Professor of Pharmacology in 1946. During the period in Cambridge he turned more to studies on urinary secretion in conscious animals. This led to the very important discovery that the major control of antidiuretic hormone secretion was by the osmolarity of the blood. This very elegant study has become one of the great classics of physiology, and was presented in a brilliantly lucid fashion in the Croonian Lectures delivered to the Royal Society in 1947. He continued to work on various aspects of the control of kidney function up to his retirement in 1961. He was then offered a research professorship in physiology at the University of Melbourne, where he spent the years 1961 to 1964 working with undiminished enthusiasm on renal problems. He returned to Cambridge in 1964 and settled down to write a book on the physiology of the kidney, in which he could draw upon his own vast experience of the subject. It was a task he was still engaged on at the time of his death. Verney was a fine teacher, and in particular the magnificent demonstrations he gave were an exciting part of his teaching. He had a great sense of fun, and there can be few of his colleagues who were not vastly entertained by his stories or stimulated by his wit. This may be illustrated by his entry in *Who's Who*: "Recreation: administration and tax evasion."



[Walter Stoneman

Many honours came his way. He was elected F.R.C.P. in 1928 and F.R.S. in 1936. After his retirement he became an emeritus professor of the University of Cambridge and an honorary fellow of his college. He was the Sharpey–Schafer lecturer, University of Edinburgh, in 1945; Croonian lecturer, Royal Society, 1947; William Withering lecturer, Birmingham, 1949; Dunham lecturer, Harvard, 1951; and elected a member of many foreign medical societies.

He is survived by his wife, Ruth Conway, whom he married in 1923, and by two sons and a daughter.—A. S. V. B.

GAETANO MARTINO, M.D.

Professor Gaetano Martino, eminent Italian physiologist and statesman, died at his home in Rome on 21 July, after a long illness. He was 67.

[Universal Pictorial

Gaetano Martino came from a distinguished Sicilian family. He was born at Messina on 25 November 1900, and graduated as doctor of medicine from the University of Rome in 1923. After a four-year period of scientific training spent at the Berlin University II Medical Clinic, the St. Antoine Hospital in Paris, the University Institute of Vegetative Physiology in Frankfurt, and in the University of London, he was appointed assistant professor of physiology at the university of Messina. From 1930 to 1934 he held the appointment of professor of physiology at the University of Asunción, Paraguay, and from 1934 to 1956 was professor of biochemistry and physiology, as well as director of the Institute of Human Physiology, at the Messina University. From 1957 until his death he held these same offices at the University of Rome. A pupil of Giuseppe Amantea—one of the most distinguished disciples of the world-famous physiologist Luigi Luciani—Gaetano Martino became a most original and versatile research worker in the fields of physiology and biochemistry. He published more than a hundred scientific papers, among which those on the hyperglycaemic factor of the pancreas and on the mechanism of reflex epilepsy are worthy of special mention.

In addition to his merit as a research worker and teacher Professor Martino was internationally known as an able politician and statesman. He was a member of the Italian Parliament from 1946 until his death, and was its vice-President between 1948 and 1954. In 1954 he was Minister of Education and from 1948 to 1957 Minister of Foreign Affairs. It was in this latter post that he displayed the full measure of his wisdom and political talent. Largely by his efforts Trieste was returned to Italy in 1954, Italy gained admission to the United Nations in 1959, and the creation of the European Economic Community and Euratom owe much to him. In 1960 he led the Italian delegation at the Geneva Disarmament Conference and also led the Italian Delegation at the United Nations General Assembly on two occasions. From 1962 to 1964 he was president of the European Parliament and from 1961 until his death was president of the Italian Liberal Party.

In recognition of his work of teacher and scientist Gaetano Martino was elected successively rector of Messina University and of the University of Rome. He was a member of many learned societies including the Accademia Nazionale dei Lincei, the Accademia Nazionale dei Quaranta and the World Academy of Art and Science. Numerous honours were bestowed upon him, both in Italy and abroad, including the Légion d'Honneur of France and the Order of Merit of the Federal Republic of Germany. He was an enthusiastic worker for the promotion of the European Economic Community and a tireless worker to secure the admission of Great Britain, as he regarded her membership as an essential factor in the process of political and economic integration of Europe.

He is survived by his wife Donna Alberta, a daughter of the Prince Stagno d'Alcontres, and by his daughter and two sons.—S. C.

J. B. S. GUY, C.B.E., T.D., D.L.
M.B., B.S.

Dr. J. B. S. Guy, formerly in general practice at Loftus, Yorks, died in the King Edward VII Hospital, Windsor, on 22 July. He was 67.

John Baden Strickland Guy was born at Widnes, Lancashire, on 5 June 1900. His early years were spent in Sheffield, and in 1912 he moved to Newcastle upon Tyne. He was educated at the Royal Grammar School, Newcastle upon Tyne, and the University of Durham College of Medicine. After a short time at the College of Medicine in 1917 he left and served in the Royal Flying Corps until the end of the war, returning to Newcastle to complete his studies, qualifying M.B., B.S. Dunelm in 1924. After qualifying he became house-surgeon to the late Professor R. J. Willan at the Royal Victoria Infirmary, and on completing this appointment he went into general practice with his uncle at Whickham-on-Tyne. After 12 months there he settled in Loftus, North Yorks, in November 1925, where except for his active service he was to practise for the next 40 years.

In spite of being in a busy single-handed practice he found time to interest himself in medical politics and in Service life. He was vice-chairman of the North Riding Territorial Association, and he served until 1940 as regional medical officer to the D.L.I., T.A. In the late 1920's he became a member of the old North Riding of Yorkshire Local Medical and Panel Committee. He was honorary secretary of the Cleveland Division of the B.M.A. from 1933 to 1938, and was voted chairman of that Division from 1938 to 1940. He was elected President of the North of England Branch of the B.M.A. from 1946 to 1947, when he became chairman of the newly formed local medical committee of the North Riding of Yorkshire. From that committee he was appointed a member of the North Riding of Yorkshire Executive Council, and was soon elected its vice-chairman. He became chairman in 1955 and remained chairman of both until his retirement in November 1965. He was elected President of the Tees-side Branch of the B.M.A. in 1953, and on the institution of the Roll of Fellows of the B.M.A. he became a fellow.

At the outbreak of the second world war Guy was mobilized with his regiment. In 1940 he was posted to the Western Desert in charge of a field hospital, and remained with the Eighth Army throughout hostilities, serving in Egypt, Libya, Sicily, Italy, Greece, and Austria. He was mentioned in dispatches in 1941 and 1943. In the same year he was awarded the O.B.E. and became A.D.M.S. to the 46th Division in Italy. In 1944 he was made a C.B.E. and was awarded the Territorial Decoration.

On retiring from his Territorial Army commitments because of age he was appointed Honorary Colonel of No. 1 General Hospital T.A., Newcastle upon Tyne—an appointment of which he was justly proud—and he was elected vice-chairman of the North Riding of Yorkshire Territorial and Auxiliary Forces Association in 1958, retiring on age in 1965. In 1959 he was appointed Deputy Lieutenant of the North Riding of Yorkshire. On the occasion of the Annual Clinical Meeting of the B.M.A. in Middlesbrough in 1960, at the unanimous request of the members of his Division, John, in spite of poor health, accepted the office of chairman for the second time and greatly helped the success of the meeting.

John was a dominant and forceful personality but never brusque. Although he led a busy life, he was always available to discuss problems and advise his patients and colleagues. In fact it became axiomatic that whenever counsel and guidance were needed we, his colleagues, invariably looked to and asked John—and his vast experience and wise counsel never failed us. He was a man who lived and enjoyed life to the full, but was happiest when he ensured that others enjoyed life too. It is regrettable that he enjoyed his retirement for so short a time. He leaves a widow, two sons, a stepdaughter, and a stepson, to whom we extend our sympathy.—W. M. M.

F. O. G. writes: I met John Guy some 35 years ago. Though not tall, he was a handsome and distinguished man. He was outspoken, but chose his words with care. On first impression some thought him to be very dogmatic, but in point of fact he was always willing to listen to argument. He was never anything but courteous; a characteristic phrase was "Let us be fair." I knew him as a colleague, a friend, and as a patient. That he was a character and a great man in the profession there is no doubt. He did much in the area for the benefit of the practitioners of his immediate vicinity in particular, but also affecting others. The present generation perhaps does not appreciate the amount of work necessitated in the past to obtain a somewhat better system than there used to be. He was worshipped by his patients. I knew of no one who disliked him. He loved a party and he was a difficult man to keep up with in his early days, such was his capacity for life.

After his wonderful military career he returned to his practice but was never really a fit man. He suffered from much pain and increasing disability. He forced himself to complete his 40 years in practice in Loftus. On retirement in November 1965 it was thought that the warm south would give him some comfort. This indeed was the case for a short time. Unfortunately he suffered from increasing anginal attacks and persistent pain from spinal arthritis.

He married twice. He leaves a widow and two children and two stepchildren, to whom our sympathy goes out. John will be remembered by all as a great character, a splendid doctor, and a wonderful friend.

W. H. HARWOOD-YARRED, B.SC. M.B.

Dr. W. H. Harwood-Yarred, a general practitioner in Colchester, Essex, died in St. Thomas's Hospital, London, on 22 July. He was 90.

William Henry Harwood-Yarred was born on 18 January 1877, and was educated at Dulwich College. He went to St. Thomas's Hospital in 1897, where he had an outstanding medical studentship, having already won the First Entrance and William Tite scholarship. At the end of his first year he won the First College prize and repeated this success in the following year. In the winter of 1901-2 his exceptional promise was evident when he won the surgery, pharmacology, and public health prizes, the Cheselden Medal, and the Treasurer's Gold Medal. He graduated B.Sc. and M.B. the same year. In 1904 he won the Murchison scholarship. He was consecutively assistant house-physician, house-physician, junior and then senior obstetric house-physician, and finally resident assistant physician. It was during the time that he was a house-physician that cases of acute appendicitis were first admitted into surgical wards. He also became intensely interested in surgery, and gained great knowledge and expertise in this field.

He bought a waning general practice in High Wycombe, Bucks, and very quickly built it up into a flourishing one and became well known throughout the northern part of the county. He was constantly called into consultation by general practitioners, and did most of the surgery in the area. In 1929 he left High Wycombe and continued practice in Colchester, where he met with equal success until his retirement at well over the age of 70.

He was a member of the B.M.A. for the whole of his medical career. He is survived by his son, Dr. Noel Harwood-Yarred, who is in general practice in Godalming, Surrey.

I first met him in 1926, when he was at the height of his ability. He was a very knowledgeable physician, a wonderful surgeon, as well as being a first-class obstetrician. He had a delightful personality, a reassuring combination of seriousness and gaiety, and could instil confidence into the most fearful of patients. My personal view has always been that he was the greatest "all-rounder" as a general practitioner with whom I have had the good fortune to be associated, and even 35 years later he is well remembered and loved in High Wycombe. —W. B.

P. S. writes: William Harwood-Yarred came to Colchester in the early 1930s to the house where Dr. William Gilbert, P.R.C.P., physician to Queen Elizabeth I and student of electricity and magnetism, had lived and practised. He was a general practitioner of wide experience. Of distinguished appearance, ever calm and courteous in manner, he had a clear analytical approach to medical problems backed by sound clinical intuition and a familiarity with current medical thought. Though somewhat retiring, he was regarded by his colleagues and patients with great affection and respect.

A. GREENHALGH, M.B., B.CH., B.A.O.

Dr. A. Greenhalgh died on 16 August at his home in Grindleton, West Riding, after a long illness. He was 62.

Arthur Greenhalgh was born in Accrington on 7 May 1905 into a medical family. His father was in general practice, and was also medical officer of health for the town, and his mother was the first matron of the Accrington Victoria Hospital. In 1930 he graduated M.B., B.Ch., B.A.O. at Queen's University, Belfast. He joined his father in practice, and eventually succeeded him. He maintained the close family association with the Victoria Hospital and served in turn as honorary anaesthetist, honorary surgeon, and after 1948 as clinical assistant in medicine.

He joined the Royal Navy in 1941, but was invalided out from the Service and spent two years in hospital before returning to practice. Ill-health dogged him throughout his career, but did not curtail his activities. Until his death he was president of the local branch of the British Empire Campaign for Cancer Research, and six years ago he was chairman of the Blackburn and District Division of the B.M.A. He was devoted to the practice of medicine and his skill and clinical acumen earned him the love of his patients and the respect of his colleagues.

Unfortunately deteriorating health brought about his premature retirement in December 1963, and he went to live at Grindleton, just across the border from his native Lancashire. Sadly he was not to enjoy his retirement for long. He suffered greatly in the last year of his life, but he bore his illness with a patience and fortitude which was sustained by the devotion of his wife and family. To his widow Ada and to his son and daughter we offer our deepest sympathy.—H. H. S.

F. D. C. FORD, B.M., B.CH. D.OBST.R.C.O.G.

Dr. F. D. C. Ford, a general practitioner in Shere, Surrey, died suddenly on 12 August. He was 39.

Frank David Chubb Ford was born on 11 June 1928 at Eastbourne. The son of a general practitioner, he was educated at Lancing College; at Hertford College, Oxford, which he entered with a scholarship in classics; and at St. Bartholomew's Hospital, London, qualifying B.M., B.Ch. in 1954. He took the diploma of the Royal College of Obstetricians and Gynaecologists in 1956 and held a number of house jobs. He then became a trainee in general practice in Surrey, and stayed to become an assistant and then a partner in the practice.

G. I. W. writes: David Ford's sudden death has stunned the whole district. We cannot yet believe he will not return from holiday to take up his energetic work among the people for whom he did so much. Many mothers and young families owe much to his obstetric skill and enjoyment of children. Among the sick of heart and mind he moved more surely than most of us. His patience and good humour in easing the burden of chronic illness and age will be missed in more than one old people's home. Truly he was a most likable young man, and still on the threshold of life. He cannot be replaced. He suffered from severe asthma all his life, and we can all learn from his example to be braver in the face of adversity. To Diana his wife, who is a doctor, and his children many helping hands will be stretched out.

W. E. H. BANKS, M.A., M.B., B.CH.

Dr. W. Banks died in Falmouth Hospital on 9 August after a short illness. He was 72.

William Eric Hallamore Banks was the son of a general practitioner in Falmouth. Eric, as he was known to everyone, was educated at Haileybury College, and Clare College, Cambridge, going on to St. Bartholomew's Hospital, London, for his clinical work. He took the Conjoint diploma in 1920 and graduated M.B., B.Ch. in 1921 from Cambridge, gaining a gold medal. In the first world war he saw service in a destroyer as a surgeon. His further surgical experience was at the Halifax Infirmary. On his father's death he returned to Falmouth to take over the practice, as there was no other successor, and from then on Eric Banks served the Falmouth area until his retirement two years ago. He was, until the advent of the National Health Service, surgeon to the Falmouth and District Hospital, and as a general-practitioner surgeon his shrewd analytical mind and his gentleness of hand brought to him a status that he never sought. He was by general acclaim a consultant in the district, and few sought his quiet wisdom without profit to both themselves and their patients. In 1942 he became Justice of the Peace in the borough of Falmouth and served the county in this capacity in 1951. He was a member of the Probation Committee as the representative of the Falmouth Petty Sessional Division from 1948 onwards, and in 1965 became chairman of this committee. He was chairman of the West Cornwall division of the B.M.A. from 1927 to 1929 and a Representative at the A.R.M. in 1934.

Those who came to know Eric Banks found that behind his grave and rather silent façade lay a Gilbertian wit and a capacity to interest his hearers that made an evening in his company a joy to remember. He had a profoundly religious philosophy of life, for he had—to his own satisfaction—examined the Christian credal propositions and found that they could be made to work. His was no narrow sectarian religion, but with an almost Franciscan indifference to the material advantages of his chosen profession he offered his skill and wisdom to humanity as they were needed.

He leaves one daughter. His wife, to whom he was devoted, predeceased him by nearly a year. Both of them will be greatly missed in a community they served so loyally and for so long.—G. E. W.

Who Decides the Standard?

[From our Legal Correspondent]

Though two consultant obstetricians and two general practitioners said they would have done what a defendant general practitioner did in treating an obstetric case, the defendant was found guilty of negligence largely on the evidence of a consultant pathologist.

Mrs. Maureen Audrey Hucks claimed damages for negligence against Dr. John Hugh Cole and Dr. Henry Gordon Peters, practising in partnership at Wellington, in Somerset, after she had contracted fulminating septicaemia following normal delivery of a child on 10 October 1963. The case was heard in the High Court in July 1967, before Mr. Justice Lawton. The case against Dr. Peters was abandoned at an early stage in the trial.

In 1963 Mrs. Hucks was aged 27 and already had two children. In August that year her fingers began to swell. On 4 October her wedding ring was filed off. At her last antenatal examination on 7 October she showed Dr. Cole a reddened area about half an inch in diameter within which there were three tiny spots, each with a yellow centre, under the site of the ring. Dr. Cole told her not to worry about them. He took no steps to find out what organisms were causing the sepsis.

The day after delivery of her child in a maternity home, on 11 October, when Mrs. Hucks was being washed, a nurse noticed the reddened area on her finger, and found another reddened area on a toe which looked like a "shoe-rub." Mrs. Hucks was at once moved into a room on her own and Dr. Cole was informed. Dr. Cole ordered a swab to be taken and sent to a pathological laboratory, and prescribed 250 mg. of tetracycline in tablet form to be taken four times a day for five days.

In the days that followed the general picture was one of healing. On 15 October, when Dr. Cole saw the patient, the finger and toe were both much improved, the finger more improved than the toe. The patient's general condition was good, and she felt well in herself. On that day Dr. Cole saw the pathological report, which showed the presence of *Staphylococcus aureus* resistant to tetracycline and *Streptococcus pyogenes.* Dr. Cole decided to continue the five-day course of tetracycline without prescribing any further drugs, and on 17 October after that course had ended he decided not to prescribe

EPIDEMIOLOGY

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **12 August** (No. 32) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars-General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

	1967					1966

* Measles not notifiable in Scotland, whence returns are approximate. † Includes primary and influenzal pneumonia. § Includes puerperal pyrexia.

(Continued from previous page)

any further drugs. The finger and toe had virtually healed, and in his view "it was all over bar the shouting." The nursing reports showed that an antiseptic powder was applied to both finger and toe on 19 October.

Onset of Septicaemia

On 19 October Mrs. Hucks was discharged. She had a pain in her abdomen shortly before she went home, and at home she became ill and was treated by Dr. Peters and then by Dr. Cole, who removed her to hospital, where a diagnosis of fulminating septicaemia was confirmed. The organism was identified as *Str. pyogenes*.

Mrs. Hucks's counsel criticized Dr. Cole on three grounds, firstly because he failed to treat his patient's finger when it was first shown to him, secondly because he failed to change the antibiotic after seeing the laboratory report, and thirdly because he discontinued the administration of antibiotics after 16 October.

Mr. Justice Lawton held that the first two charges of negligence failed. Although Mr. Alec Bourne, Professor F. E. Camps, and Dr. H. B. May all had expressed the view that on seeing the laboratory report Dr. Cole ought to have prescribed penicillin to combat the streptococci and either cloxacillin or erythromycin to combat the staphylococci, Mr. Justice Lawton held that Dr. Cole was not negligent in the light of the experience found in Somerset in October 1963.

So far as the third allegation was concerned, Miss Josephine Barnes, Mr. James Thomson, and two general practitioners practising in the West Country said that they would have decided as Dr. Cole did had they been faced with the same critical situation. But the court accepted Dr. May's evidence that it was wrong to discontinue the treatment of an infection in a patient in the puerperium until one was sure that the patient was not still at risk from infection, and that organisms on the finger are much more dangerous than organisms elsewhere. A responsible practitioner would make sure that the patient was not at risk until the involution of the uterus was complete.

Damages were awarded against Dr. Cole in the sum of £2,500 with costs, with a stay of execution pending an appeal.

MEDICAL NEWS

British Scientists Share U.S. Award

Two British biochemists, Dr. George J. Popják, M.D., F.R.S., and Dr. J. W. Cornforth, F.R.S., are to share with two Continental scientists an award of $50,000. The Stouffer Prize was established last year by Mr. Vernon Stouffer, a Cleveland businessman, to promote research into reducing heart attacks and strokes. The award to Dr. Popják and Dr. Cornforth is for "their team effort in research into hardening of the arteries." For many years they have worked together on basic chemical studies related to life processes. Both have been members of the scientific staff of the Medical Research Council. In 1962 they were appointed joint directors of a new chemical enzymology unit set up by the Royal Dutch/Shell Group. The scientists with whom they share the award are Dr. V. S. von Euler, of Stockholm, and Dr. Peter Holtz, of Frankfurt. (Photographs by Shell Photographic Unit.)

Dr. G. J. Popják

Dr. J. W. Cornforth

Society of Apothecaries of London

At a meeting of the Court of Assistants of the Society of Apothecaries of London on 14 August Dr. Hugh M. Sinclair was elected Master, Mr. Henry R. Thompson Senior Warden, and Dr. Peter M. F. Bishop Junior Warden.

Allen and Margaret Wilson Memorial Fund

A memorial fund has been launched to commemorate the work of Dr. Allen Wilson and his wife, Dr. Margaret Wilson, who were killed in an accident on the A1 in June.

The objects of the fund are (*a*) to encourage the development of any young person from the parishes of Innerleithen, Traquair, and Walkerburn through recurring prizes of grants; and (*b*) in alternate years to make an award to a country family doctor for original or important work.

Cheques should be made out to the Allen and Margaret Wilson Memorial Fund and sent to Dr. E. V. Kuenssberg, 15 Warriston Crescent, Edinburgh 3, or to the Manager, Bank of Scotland, Innerleithen, Peeblesshire.

Cannabis Synthesis

Two teams of chemists report the synthesis and isolation of biologically active constituents of hashish in the current issue of the *Journal of the American Chemical Society* (16 August, pp. 4451 and 4452). T. Y. Jen and his colleagues, of Wyeth Laboratories, Philadelphia, report the total synthesis of tetrahydrocannabinols, and a different method of synthesis is reported by R. Mechoulam and his colleagues working in Israel. The latter team refer also to a third method of synthesis carried out by T. Petrzilka in Zurich. The compounds yielded by these latest syntheses differ from those produced by earlier methods in that they are suitable for biological experiments to study the effects of hashish.

Paediatric Surgeons

The British Association of Paediatric Surgeons held its 14th international congress in Bremen from 18 to 21 July. Over 260 surgeons from 39 countries took part. Professor Fritz Rehbein gave the Isabella Forshall lecture on paediatric surgery in Germany. An extensive scientific programme included groups of papers on the measurement of bladder and anal functions and on aspects of the postoperative behaviour of the neonate. Receptions were given by the Prime Minister of Land Bremen and various professional societies. Among the guests at the annual dinner was Sir Frank Roberts, British Ambassador to the Federal Republic of Germany.

On 24 July an honorary degree was conferred on Mr. P. P. Rickham, president of the association, by the faculty of medicine of Göttingen University. Mr. F. H. Roberts was elected president for 1969–70.

Newcastle Curriculum

The Nuffield Department of Industrial Health refers in its fourth quinquennial report to the contribution it is making to the new curriculum adopted by the Newcastle Medical School. At the start, in the first stage, two lectures are given on the importance of industrial geography in determining health and work. In the second stage there is a course of lectures (11 hours) on the occupational hygiene of the industrial environment, also on clinical methods. Students are examined at the end of it orally and in writing. In the third stage the teaching is organized in relation to the physiological systems of the body. Formal teaching is supplemented by factory visits. In addition, students can undertake a piece of research under the special study project scheme. At the end of the third stage Part 1 of the final M.B., B.S. is taken.

Society for Research into Hydrocephalus and Spina Bifida

The Casey Holter Memorial Prize for the best essay reporting original work bearing on the pathogenesis or treatment of spina bifida or infantile hydrocephalus was awarded to Dr. A. J. Barson, of the department of pathology, Manchester University, for his essay on "Spina bifida; the significance of the level and of the extent of the defect to the morphogenesis."

Studentship for Medical Research

The Council of St. John's College, Cambridge, invite applications for a Meres Senior Studentship for Medical Research. See advertisement on page xxxiii.

Exhaust Pollution

In 1965 petrol-driven vehicles in Britain discharged 5m. tons of carbon monoxide into the atmosphere. Diesel engines added a further 80,000 tons. These estimates are given in a report on air pollution from road vehicles prepared by the technical committee of the National Society of Clean Air (3s.). It is difficult, according to the report, to determine the effects on human health of pollutants emitted from motor vehicles—firstly, because there is no specific air pollution disease ; secondly, because it is not possible to isolate the effects of motor-vehicle emissions from those from other sources ; and, thirdly, because some of the pollutants emitted by motor vehicles are emitted from other sources as well. "For these reasons the determination of cause and effect is beset with statistical pitfalls." The report considers that for petrol engines modified carburettors and fuel injection systems offer most hope for reductions in carbon monoxide and hydrocarbons. The way is now open, it says, for a standard European method of testing the emission of carbon monoxide, and it urges the Ministry of Transport to fix limits for its content in exhausts. It also suggests that exhaust gas analysis and carburettor adjustments should be included in annual car tests. Commenting on a forthcoming British Standard on diesel engines, the society criticizes the smoke level adopted and calls for a lower level. "There is no point," it adds, "in setting a standard if the smoke level chosen is appreciably above current practice with many existing vehicle engines." (See leader at p. 570.)

New Journal

The *Journal of Communication Disorders* is published quarterly by the North-Holland Publishing Company (P.O. Box 103, Amsterdam). It is concerned with experimental research, also with clinical and theoretical contributions. The general policy is to accept only articles that add to knowledge. Subscription £5 10s. ($15) a volume, post free.

People in the News

▶ Dr. J. H. F. BROTHERSTON and Dr. JAMES H. WEIR have been made honorary Fellows of the Royal Society of Health in recognition of their contributions to the promotion of health.

▶ LORD COHEN OF BIRKENHEAD is to be the first patron of the Association of Sea and Air Port Health Authorities.

LONDON SATURDAY 9 SEPTEMBER 1967

Pointers

Rubella in Pregnancy: Gammaglobulin given before exposure to infection gave some protection against foetal abnormalities in a series report by Professor J. C. McDonald and Dr. Catherine S. Peckham (p. 633). An investigation on behalf of the Public Health Laboratory Service revealed that a second prophylactic dose of gammaglobulin did not increase maternal protection from infection (p. 638).

Hyaline Membrane Disease: Correcting acidosis by intragastric route resulted in fewer deaths than scalp-vein infusion in clinical trial conducted by Drs. J. M. Abraham and R. J. K. Brown (p. 640). Leader (p. 628).

Differential Diagnosis of Hallucination: Involvement of cerebral cortex by occlusive vascular disease produced formed visual hallucinations in two patients seen by Mr. C. T. Hart (p. 643).

Lactation and the "Pill": Oral contraception initiated in the postpartum period did not cause inhibition of lactation in Dr. Teit Kærn's cases from Copenhagen (p. 644).

Sequential Contraceptives: Leader on this page.

Spontaneous Gangrene: Depression of spontaneous plasma fibrinolytic activity demonstrated by Dr. A. G. G. Turpie and colleagues in three African children affected with symmetrical gangrene of fingers and toes (p. 646).

Treating Urinary Infection: Drs. R. N. Grüneberg and W. Brumfitt found one dose of long-acting sulphonamide as effective as a seven-day course of ampicillin, and side-effects were more troublesome with the latter (p. 649). Leader (p. 629).

Diabetic Retinopathy: Dr. P. R. Hunter and colleagues found no beneficial effect from treatment with the anabolic steroid methandienone (p. 651).

Poisoning in the Home: Digitalis glycosides (pp. 660 and 661). Management of children who accidentally eat antidepressant pills (p. 663).

Clinical Reports: Fibrinolytic activity during sickle-cell crises (p. 653). Thrombus in thoracic aorta causing embolism (p. 655). Renal damage from excessive antacid intake (p. 656). Spinal cord degeneration in spite of vitamin B_{12} treatment (p. 657). Irreducible posterior dislocation of the elbow (p. 659). Monkey parasite infecting humans (p. 659).

Health Centres: Progress at Hythe Medical Centre (p. 672); G.P. reaction (p. 683).

University Students: Morbidity (p. 674).

Bedwetting: New alarm (p. 676).

Home Dialysis: Letter on National Kidney Centre (p. 680); leader (p. 631).

B.M.A. Career Service: Information about opportunities in medicine (*Supplement*, p. 128).

Which Pill?

The doctor prescribing oral contraceptives may well be confused by the large number of products available, and the manufacturers' literature, with its mass of conflicting data, does not always help. Recently the range has been increased by the introduction of sequential formulations in which an oestrogen only is given early in the cycle and a progestogen is added for the last few days. This sequential regimen is claimed to be more physiological and to produce fewer side-effects, but it is reputed to be less efficient. How does it compare ?

World-wide experience has shown that for all population groups combined drugs provide the most efficient method of contraception known. They are virtually 100% effective when taken properly. The possibility of patient error has been reduced by the 21-day regimen and by ingenious packaging which makes it impossible for even the most casual or careless woman who can read to make much of a mistake. Experience with the sequential method, however, suggests that it is not and possibly never can be quite so effective. It depends for its efficacy on inhibition of ovulation, and does not make the cervical secretions hostile to sperms nor the endometrium inadequate for implantation—both of which characterize the action of the combined drugs and provide additional anti-fertility factors which are brought into play if ovulation occurs. The effect of oestrogen on ovulation varies with the dosage—a small dose is stimulating, an intermediate dose delays ovulation, and a large enough dose inhibits it. The dose of oestrogen required for consistent inhibition of ovulation shows individual and population differences. For British women 0.05 mg. of ethinyl oestradiol is an inadequate dose[1] (sequential formulations at this dosage give about 20 pregnancies per 100 woman-years), though it is apparently adequate for Mexican women.[2] With formulations containing 0.075 mg. of ethinyl oestradiol the pregnancy rate falls[3] while the best results have been obtained with 0.1 mg.[4] Other sources of error with sequential therapy stem from the need for the different tablets to be taken at the right time, particularly where placebo tablets are included and where breakthrough bleeding occurs. There is no evidence that missed tablets make pregnancy any more likely with sequential formulations than with the combined drugs.

As the mode of action of oral contraceptives becomes more clear it seems likely that the combined drugs act by inhibiting the peak of luteinizing hormone (L.H.) without affecting follicle stimulating hormone (F.S.H.), whereas when ovulation is inhibited by oestrogen—as in sequential regimens—F.S.H. is suppressed and L.H. probably not affected.[5] When treatment is given with combined drugs containing less progestogen and more oestrogen presumably the mechanism of action changes from suppression of L.H. to that affecting F.S.H. Since F.S.H. is produced early in the cycle, it is possible that day five is not early enough to give oestrogen to suppress ovulation with certainty, and claims have been made that giving oestrogen from day one increases the

efficiency of the sequential method. However, as pregnancies with sequential formulations tend to occur in later cycles as a result of breakthrough ovulation it will be some time before these claims can be substantiated. Meanwhile where maximum efficiency is required the combined drugs should clearly be the choice, for one of the main advantages of oral contraception is the complete freedom from anxiety of unwanted pregnancy.

Most of the common side-effects of oral contraceptives are related to the oestrogen/progestogen balance, and any one or more can occur as the effects of a woman's own menstrual cycle, menopause, or normal pregnancy. These symptoms may therefore be either produced or relieved by medication with oral contraceptives. Any product which is "too progestational" for a particular patient would produce symptoms such as discomfort in the breasts, acne, cramps in the legs and abdomen, depression, or decreased libido, and a change should be made to one which is on balance more oestrogenic—that is, containing a higher dose of oestrogen or a lower dose of progestogen or both. Similarly any one which is too oestrogenic will produce symptoms such as breakthrough bleeding, menorrhagia, oedema, tiredness, troublesome varicose veins, tension and irritability, mucorrhoea, and gastric disturbances, and a change should be made to a more progestogenic product. Claims have been made that sequential preparations give a lower incidence of side-effects. It is true that some women feel better on the variable hormonal milieu offered by sequential medication, but it is equally true that some women who have oestrogenic side-effects on sequential preparations feel much better on a more progestogenic combined oral contraceptive. The spectrum of side-effects with the more strongly oestrogenic products differs from that with the more progestogenic products and it is misleading to compare only side-effects at one end of the spectrum.

While there are advantages in using as low a dose as is compatible with efficiency and good control of the menstrual cycle, the claims that with new products or formulations side-effects are fewer than with existing products should be met with a degree of scepticism. Widespread acceptance and the reduction of anxiety over the use of oral contraceptives among doctors and women alike have resulted in fewer recorded side-effects in recent clinical trials. Such results cannot be compared with the results of earlier trials.

Though in practice many women adjust satisfactorily to any product, it can be useful in choosing a product for a particular patient to assess her hormone balance—whether predominantly oestrogenic or progestogenic—and prescribe accordingly. In this way it should be possible to eliminate her own menstrual troubles without precipitating others.

Management of the Idiopathic Respiratory Distress Syndrome

The idiopathic respiratory distress syndrome (hyaline membrane disease) remains one of the major unsolved problems of the neonatal period. Its precise aetiology continues to elude us and its treatment is the subject of controversy. At present treatment is based on the fact that it is a self-limited illness of some days' duration, and the objective is, so far as practicable, to neutralize the physiological and biochemical disturbances in order to keep the infant alive until spontaneous recovery occurs.

The disturbances that affect the baby include a lowered arterial $\mathrm{Po_2}$, a raised $\mathrm{Pco_2}$, and a metabolic acidosis which is secondary to the respiratory failure. In untreated cases hyperkalaemia develops between 12 and 60 hours of age, with electrocardiographic changes. The low arterial $\mathrm{Po_2}$ is due largely to inadequate pulmonary perfusion owing to the shunting of venous blood past the gas-exchanging areas of the lungs.[1] This may be due in part to intrapulmonary shunting, and in part to shunting of blood from right to left through the foramen ovale in the heart as a result of an increased pulmonary vascular resistance, which causes also a poor pulmonary blood flow.[2] The accumulation of CO_2 which results in a raised arterial $\mathrm{Pco_2}$ is related to the fact that in these infants the functional dead space is very large and may, indeed, approach the tidal volume.[3] The severity of these disturbances can vary widely from case to case.

In mild cases with moderate tachypnoea and sternal recession, and when cyanosis can be abolished in 40% oxygen, the prognosis is good. The principal requirements are incubator care, including carefully monitored oxygen concentrations of less than 40% and humidity over 80%, plus antibiotic cover. In the severe cases with great respiratory distress and sternal recession, cyanosis which disappears only in high concentrations of oxygen, and with large departures from normal of blood gas tensions and acid–base balance the mortality rate is about 45% unless more active treatment is given. The first essential is to raise the oxygen concentration in the incubator high enough to abolish cyanosis. Indeed, it is now the practice in several centres to catheterize an umbilical artery and to control the oxygen concentrations by periodic measurements of the $\mathrm{Po_2}$. R. Usher[4 5] was the first to claim a significant reduction in mortality from the administration of glucose and sodium bicarbonate by continuous infusion through a scalp vein. J. H. Hutchison and his co-workers[6] reported a substantial reduction in mortality when larger doses of sodium bicarbonate were given by periodic injection through the umbilical vein, controlled by frequent estimations in the blood of the *p*H, $\mathrm{Pco_2}$, plasma standard bicarbonate, and base excess.

These workers also gave fructose in preference to glucose. Others have preferred the amine buffer THAM (trometamol) to bicarbonate because of its greater alkalinity and ability to lower $\mathrm{Pco_2}$,[7] though Hutchison and his colleagues thought that it had little advantage over sodium bicarbonate and carried greater risks. However, those who believe that death from the respiratory distress syndrome is due primarily to hypoxia, and that the prognosis is influenced more by the $\mathrm{Po_2}$ than by the $\mathrm{Pco_2}$ or blood *p*H, have found it difficult to understand why correction of the acidaemia with alkali or buffer should often appear to be beneficial in severe cases with respiratory failure. Part of the explanation may lie in the recent demonstration by J. M. Gupta and co-workers[8] that there is a considerable and often sustained rise in Po_2 after the injection of THAM into the umbilical vein. This effect must be due to a diminution of right-to-left shunting of blood, presumably the result of a direct effect of THAM or alkali in the lung, with lowering of the pulmonary vascular resistance. The administration of THAM via an umbilical artery instead of the vein had a much less beneficial effect.

This week in the *B.M.J.* Drs. J. M. Abraham and R. J. K. Brown report their results (page 640) of a clinical trial designed to compare intravenous (scalp vein) with intragastric administration of glucose and bicarbonate. Surprisingly, the infants who received their fluids by stomach tube had a somewhat lower mortality rate, though the difference was not statistically significant. It is, however, difficult to assess the possible harm of handling small, oedematous, premature infants in the manner which scalp vein infusions often entail. The use of the umbilical vein for intravenous fluid therapy carries some risk of phlebothrombosis in the portal vein, but this complication seems to be rare, and catheterization of either umbilical vein or artery involves a minimum of handling or exposure of the infant. Thus, while there is some evidence that correction of the metabolic acidosis by infusions of bicarbonate or THAM, and of fructose or glucose, under careful laboratory control does reduce the mortality rate, further studies are required to determine the precise effects of these substances and the best way of giving them.

The paramount importance of the accurately controlled administration of oxygen cannot be overstressed. Theoretically, hyperbaric oxygen should have advantages in the worst cases, but in both Glasgow[9] and Boston[10] it was found disappointing in practice. It cannot, of course, relieve CO_2 retention because of the great increase in functional dead space. Assisted respiration by intermittent positive[11] or negative[12] pressure is being tried in some centres for the treatment of deteriorating patients in whom the arterial Po_2 cannot be maintained at a safe level in 100% oxygen, or when the Pco_2 rises and stays above 70 mm. Hg, and especially when there are apnoeic attacks. It is not yet possible to assess the value of these very complicated and time-consuming techniques, which are by no means free of danger.

While there is room for controversy about the best methods of treatment of the respiratory distress syndrome, it is clear that the best results will be obtainable only in centres that can undertake throughout the twenty-four hours of the day the highly complex laboratory and therapeutic techniques required. They cannot be provided in every maternity unit, and these very ill babies should be transferred to a few special neonatal units which are staffed and equipped for this type of work. The portable incubator has made the transfer of the ill newborn baby a relatively simple matter, and each area should have an "infant flying squad" for this purpose.

Single-dose Treatment of Pyelonephritis

In the study reported by Drs. R. N. Grüneberg and W. Brumfitt at page 649 of the *B.M.J.* this week the effect of a single dose of 2 g. of the very long-acting sulphonamide sulphormethoxine (Fanasil) was compared with that of ampicillin given in 500-mg. doses three times a day for seven days. Each treatment was successful in 22 out of 25 patients (88%). The two groups were comparable in age and sex, in frequency of a past history of urinary infection, which was obtained in a majority, and in that all had either an *Escherichia coli* or a *Proteus mirabilis* infection. Such good results could not be expected in infections due to other coliform bacilli (*Pseudomonas, Aerobacter,* and *Proteus* species other than *P. mirabilis*) or *Streptococcus faecalis* when treated with a sulphonamide. Side-effects were experienced by nine patients on ampicillin and by only two on sulphormethoxine, which was thus well tolerated, though, as the authors mention, larger doses have recently been found to produce skin reactions.

It is not claimed that sulphormethoxine gives better results than other sulphonamides. Another recent study[1] is mentioned in which a 90% cure rate was achieved with sulphadimidine. The advantages of sulphormethoxine are convenience, economy, and particularly the assurance that a full week of therapeutic effect will be secured, for patients instructed to take drugs daily sometimes omit to do so as soon as their symptoms are relieved. This is a leading advantage which has always been claimed for long-acting sulphonamides, though for most of them the claim has simply been that it is easier to remember one daily dose than three or four. There is the corresponding drawback that should any sensitivity reaction occur it is bound to be prolonged. This drug cannot, like another new sulphonamide, sulphasymazine, be eliminated more rapidly by alkalinizing the urine,[2] nor can it be surgically swabbed out of an injection depot, a treatment which might seem appropriate for such a severe and prolonged reaction to benzathine penicillin as that reported by H. C. Anderson.[3] Sulphormethoxine has not yet been used long enough to decide whether it shares the liability of other long-acting sulphonamides to produce the Stevens-Johnson syndrome, and Grüneberg and Brumfitt are probably wise in suggesting that it should not be administered to children until more experience with it has been gained.

Of the 50 patients treated 16 given ampicillin and nine given sulphormethoxine had a blood antibody titre against infecting organisms considered to be high enough to indicate renal involvement. This is a point of vital interest, because the effect of this sulphonamide must be exerted mainly in the tissues. Its half-life being about seven days, 1 g. of the dose given would be diluted in at least 10 litres of urine passed during that time, giving a concentration of at most 10 mg. per 100 ml., lower than that present in the blood. In ladies fond of their cups of tea (there is no mention of fluid restriction) the volume of urine passed in a week could have been considerably greater and the concentration of drug consequently lower. Even 10 mg. per 100 ml. seems inadequate for an antibacterial effect, particularly when acting on such large numbers of organisms as occur in infected urine. It therefore seems that these patients, in so far as their recovery was due to the treatment given (presumably some would have recovered spontaneously), owed it to the action of the drug in the tissues and not in the urinary tract. No such distinction need be made for ampicillin, which attains high concentrations in the urine as well as an adequate tissue level.

The question whether an action in the urine or in the tissues is more important has been argued for years. Clearly a tissue effect must be exerted when the substance of the kidney is affected. On the other hand, innumerable patients have incontestably been cured with mandelic acid or nitrofurantoin, neither of which attains an effective concentration except in the urine. The same is probably true of nalidixic acid. Is it to be concluded that in all these patients the kidney is not involved, and other tissues only superficially? The most difficult thing to explain is the similar proportion of successes claimed for drugs having different sites of action in unselected series of cases. Some act in both tissues and urine, several only in the urine, and here we have in sulphormethoxine one apparently incapable of exerting much effect except in the tissues. Yet it was successful in patients without as well as with evidence of renal disease. There is much in this subject which still remains to be explained, and it is not likely to be so except by the application of new and more searching methods to the study of patients undergoing treatment.

Chlorpromazine Melanosis

A side-effect of prolonged treatment with chlorpromazine is oculo-dermal melanosis.[1-3] In this condition the areas of skin exposed to sunlight become excessively pigmented and develop a violaceous or slaty-grey colour in the more severe cases. In the eye the lens, cornea, conjunctiva, and retina are affected.

The first changes usually occur in the lens. Brown or white granules are deposited under the anterior capsule in the pupillary area, and they may progress to form a disc- or star-shaped opacity. Granules also appear in the deeper layers of the cornea around Descemet's membrane; in some they appear also in the epithelium and anterior stroma. The early lens and corneal changes may be visible only with the slit lamp, but later they can be seen with an ophthalmoscope or the unaided eye. Pigmentation is also seen in the bulbar conjunctiva in the palpebral fissure. While no fundal changes were found in most of the surveys carried out[4-8] a few cases have been reported with clumping of pigment at the periphery of the retina or at the macula.[9-11] Some of these patients would have had more than one of the phenothiazine group of drugs, of which thioridazine in particular is a well-recognized cause of pigmentary choroido-retinopathy, but the rest of the patients had received only chlorpromazine.

These ocular changes have caused visual impairment in only a few cases.[5 9] In most of the surveys carried out no visual defects were found, though this may have been due to a lack of co-operation by the patients.[4-8] Electrodiagnostic tests of retinal function have generally been reported as normal,[5 11] but some cases with retinal changes had reduced potentials.[10] The pathological changes occurring in the skin[2] and conjunctiva[9] have been shown by biopsy to consist of clumps of pigment, with the staining characteristics of melanin, clustered round the blood vessels in the dermis. No other pigment has been found histologically, but reflection spectrophotometry[12] suggests that while in the mild cases the pigment was melanin in the more severe ones there was some other pigment present as well. Electronmicroscopical reports are conflicting. One author found[13] the typical appearance of melanin in the skin with some additional osmiophilic particles in the endothelial cells of the blood vessels of the dermis, while another author[14] found no "natural" melanin in the dermis. Lens changes have been produced in guinea-pigs by the administration of chlorpromazine and irradiation with ultra-violet light; extracts of these lenses together with the cornea showed a high concentration of the drug.[15]

So it would seem probable that both melanin and a drug metabolite are deposited in the skin and eye to cause the observed changes. In several post mortem examinations carried out on patients who died suddenly while on chlorpromazine therapy it was found that all the internal organs were heavily infiltrated with melanin,[16] and it has been suggested that infiltration of the heart may cause irregular rhythm, resulting in death. Tests of renal and hepatic function are often abnormal in patients on chlorpromazine therapy.

The condition has been described mainly among the inmates of mental hospitals because it occurs in patients who have taken large doses of chlorpromazine for long periods. The ocular changes seem to be clearly related to the amount of drug given and also to the daily dose.[17] While early reports suggested that affected patients had taken at least 500 g., later reports showed that melanosis could occur after smaller amounts.[6] Some investigators believe that the side-effects are not common if the daily dose is small, even if more than 500 g. are given.[7 18] The side-effects are almost certainly related to the concentration in the body of chlorpromazine,

and one patient with uraemia developed marked pigmentation after 34 days when on a dose of 75 mg. a day.[19] The incidence of ocular changes is variously reported as between 20% and 39%,[6 11] and the frequency seems to depend on the concentration of ultra-violet light[20] as well as the drug dosage. The skin pigmentation is believed to be a phototoxic reaction caused by the chlorpromazine which has been shown experimentally to cause more reaction to ultra-violet light than the other phenothiazine drugs in common use.[21] Acute photosensitivity has been reported in a few cases, with erythema and blistering of the skin.[22] The melanosis was originally thought to be confined to women with amenorrhoea,[1] but later the sex incidence was found to be equal,[11 23] and because of the similarity between this melanosis and endocrine melanodermia it has been suggested that the endocrine system is involved. One theory is that chlorpromazine affects the pituitary gland and increases the production of melanocyte-stimulating factor.[24] Another is that the formation of adrenaline and noradrenaline is blocked, so that excess melanin is produced,[16] but estimations have shown the catecholamines in the urine to be normal.[11] A. C. Greiner and G. A. Nicolson[16] have suggested that the production of melatonin, the pigment-lightening factor in the pineal gland, is inhibited, and in some necropsies the pineal body was found to be atrophic. As an interesting outcome of these investigations the authors also found abnormal pigmentation and pineal atrophy in schizophrenics who had not had chlorpromazine. They therefore suggested that there may be an intrinsic abnormality of the pineal gland in schizophrenia and the blockage of melatonin production causes formation of a hallucinogenic compound.[25] Stopping the drug does not reverse the skin or eye changes.[26] Attempts to reduce the skin pigmentation with D-penicillamine have been encouraging.[26 27] This compound will chelate copper, which is concerned in the synthesis of melanin. Keeping the patients in the dark also reduced the pigmentation.

Thus it seems that these changes will occur when chlorpromazine in high dosage is continued for years, but the amount of visual trouble caused does not at present seem to be very great, so that the benefits of treatment outweigh the disadvantages. The possibility of its causing death by deposition in the internal organs has not yet been fully evaluated.

Closure of Kidney Centre

The difficulties in which the National Kidney Centre in North London now finds itself have to be seen against a background of general scarcity of skilled staff. The decision to close the centre, previously announced,[1] has apparently not been irrevocably taken. For Mr. Murray Medway, one of its founder trustees, states in our correspondence columns this week (page 680) that the centre could continue to function if a replacement for its present director, Dr. S. Shaldon, were found. Dr. Shaldon's resignation takes effect from 1 July 1968.

Dr. Shaldon has stated[2] that he hoped from the outset the centre would be able to co-operate with the N.H.S. dialysis programmes whenever possible, to ensure the advancement of this form of treatment. And he attributes the failure of the venture to "the inability to find a suitable formula to bridge the dogmatic distinction separating medical practice inside and outside the N.H.S."

He and other workers have shown that patients can be trained to dialyse themselves in their own homes with the minimum of help from a relative.[3] Such patients are taught to prepare, check, and sterilize the kidney and other equipment, disconnect the arteriovenous shunt, make the connexion to the kidney, and administer heparin as required. It is claimed that there are actually fewer technical failures of dialysis in the home, presumably because in these circumstances the prescribed routine is scrupulously followed. If the shunt should clot it can be freed of clot by the patient or his relative. All disposable material, dressings, dialysate concentrate, heparin, and the rest can be supplied under contract to the patient, so that when all is going smoothly—and that needs emphasizing—the patient is completely independent of the training centre, and does not require support from it other than occasional advice by telephone. The dialysis equipment has to be maintained in perfect order by the manufacturer.

But what is to happen to such a patient when complications arise, as they are certain to do sooner or later? The arteriovenous shunt will not last indefinitely. The standard of care of the shunt may be very high in the home, but from time to time shunt infections occur, and these may be dangerous, even potentially lethal, infections, which must be promptly and vigorously treated. Patients whose shunts repeatedly clot may need long-term treatment with oral anticoagulants. This will require regular supervision, and may lead to haemorrhagic attacks necessitating admission to hospital.[4] When the shunt fails the venous or arterial end must be dealt with or a complete new shunt inserted. Before undertaking the placement of a new shunt it may be necessary to carry out radiological studies of the vessels of the limb to be used. For these and other eventualities related to the treatment the patient will need to be admitted to hospital, preferably to a centre providing intermittent haemodialysis. Patients receiving dialysis in the home are not immune to ordinary illnesses and will need medical or surgical treatment for these without interruption of their dialysis programme.

It is difficult to envisage a scheme which, without prejudice to other patients undergoing intermittent dialysis completely under the N.H.S., will enable a patient to provide and pay for his own treatment when all is proceeding smoothly, yet become dependent on the N.H.S. when things go wrong. Owing to the dearth of highly skilled staff, centres providing dialysis under the N.H.S. are unlikely in the foreseeable future to have sufficient facilities to undertake treatment at short notice, and often for an indefinite time, of patients originally treated in an independent specialist centre. It has been stressed that hospitals providing dialysis centres must include beds to which their patients can be admitted when necessary. It is unlikely that sufficient beds with their supporting services will be provided to cope with an unknown and fluctuating load of patients from independent centres.

Intermittent dialysis is increasingly being regarded as a staging post on the way to kidney transplantation. The patient with a successful kidney graft is fitter and freer from restrictions than even the most successfully dialysed patient. If transplantation is accepted as the ultimate aim patients being treated by a complete renal unit will be in a better position than those treated from an independent centre. So limited are skilled staff at present that it does not seem possible to maintain a half-way position between private medicine and the N.H.S. where intermittent dialysis is concerned, though it might become so if a complete renal unit was established providing not only training in dialysis but laboratory facilities, a comprehensive aftercare system, private hospital accommodation, and such extra medical and surgical treatment as might be required.

Role of the Married Nurse

It is widely believed that in the near future there will be few spinsters over the age of 20, and that hospitals which have in the past been largely staffed by these will have to depend on married women. A recent report[1] by the Dan Mason Research Committee supplies some of the facts about the situation which have hitherto been lacking.

A questionary was sent to a sample of nurses who qualified for the *Register* in 1950 and 1959, and for the Roll in 1950, 1954, and 1959. Only half the forms were returned, but 5,974 completed the questionary, and supplied information on their marital status, whether they were working, and, if so, whether they were nursing. Those who were employed received a longer questionary on their future plans about nursing and what inducements might bring them back to hospital or domiciliary work.

There will be few surprises in this report for those familiar with the problems of maintaining the nurse establishment in hospital, except perhaps that 25% of those who answered were still unmarried, so that spinsters are still not uncommon. Nurses in Britain have a firm belief that the welfare of a young family depends on the presence of the mother, and three-quarters of those who had children under 5 were not working.

The longer a nurse's break of service, the less likely she is to return to hospital, and this is perhaps a consequence of the pace of technical advance. Of those who planned to go back to nursing 83% were under 40 years old, though this group formed only 46% of the total. Nearly a half of the registered nurses and over a third of the enrolled were not in paid employment, but those who were working were nearly all engaged in nursing full- or part-time. Many of the older and married women were working outside hospital, and the expansion of domiciliary and public health work is seen as a way of relieving pressure on hospitals.

The most useful part of the report to hospital administrators should be that on deterrents to recruitment and proposals that would encourage return to nursing. There was general agreement on these in all the groups of nurses questioned. Choice of working hours and flexibility to meet family commitments were always at the top. There is no doubt that if planners are able to spend time and thought on duty rosters it is possible to fit in numbers of part-time and married staff, but it is also true that if unmarried nurses are asked to work an undue proportion of evenings, weekends, and public holidays staff relations are bound to be difficult.

Refresher courses had high priority on all lists, as did the provision of crèches and nurseries. Pay was mentioned only by about a third, but the fact that after a break of service the nurse starts again at the rate of a first-year staff-nurse was a constant grievance, and it ought to be one easy to remedy in a manner fair to everyone. Opportunities for promotion and equality of status were often wanted, and it is evident that married and part-time staff are not always integrated without friction.

One point that office sisters do not always remember is that part-time staff need permanent positions, and that if they get them their satisfaction in the job and their morale rise, so that absenteeism is less. It seems probable that patterns of nursing service in Britain are likely to follow those of the United States, where large numbers of married nurses work. It may therefore be appropriate to end with a quotation from an English nurse working in America: "Eight hours nursing, eight hours with the family, and eight hours sleep works very well."

Allergy to Seminal Fluid

Acute anaphylaxis after sexual intercourse must be extremely rare. B. N. Halpern and his colleagues[1] have recently reported the case of a young woman who developed an anaphylactic response due to the presence of reaginic antibodies in her serum directed against a normal mucoprotein in human seminal fluid. The patient had no previous history of allergy, though she came from a highly "atopic" family—her mother had a long history of asthma and atopic eczema, a twin brother suffered from contact dermatitis, and a younger sister from atopic dermatitis. After her first sexual experience the patient developed generalized urticaria, oedema of the lips, eyelids, tongue, and pharynx, severe asthmatic dyspnoea accompanied by congestion of the mucous membranes, violent pelvic pain with uterine contractions, and general malaise culminating in loss of consciousness. Most of the symptoms recurred after every coitus; they reached a maximum within 15 to 30 minutes and took 24 hours to subside. The reaginic antibodies were of such high titre that seminal fluid diluted to one in a million still elicited a weal and flare reaction in her skin. Prausnitz–Küstner (P–K) reactions could be produced in normal subjects when her serum diluted as much as 1:100 was injected intradermally followed 24 hours later by seminal fluid. Passive anaphylaxis could also be obtained in monkeys. The antibodies did not react with spermatozoa and the patient had no other types of antibodies such as sperm agglutinins[2] or any "blocking" antibodies reacting in complement fixation, precipitation, or tanned red cell agglutination. Desensitization treatment with seminal fluid was tried in an attempt to induce such blocking antibodies, which are said to improve clinical symptoms in reaginic allergies, but it was unsuccessful in this patient. Chromatographic and electrophoretic separations of seminal proteins showed the antigen to be in the most basic fraction and the richest in sialic acid.

It was found that the P–K activity could be removed by precipitation with anti-IgA, and Halpern and his colleagues suggested, therefore, that the reaginic antibodies were in the patient's IgA globulins. The detailed and careful work of K. Ishizaka and his colleagues[3-6] strongly suggests, however, that reagins are in a newly defined class of immunoglobulins named IgE. These globulins have the same light chains as all classes of Ig but have antigenically distinct heavy chains with the unique capacity to adhere to cell surfaces, particularly of the mast cells and basophils which release the pharmacological mediators of anaphylactic hypersensitivity.

Gammaglobulin in Prevention of Rubella and Congenital Defect: A Study of 30,000 Pregnancies

J. C. McDONALD,*† M.D.; CATHERINE S. PECKHAM,* M.B., B.S.

WITH THE ASSISTANCE OF JUDITH MUNK

Brit. med. J., 1967, 3, 633–637

Gammaglobulin has been available to doctors in England and Wales since 1954 for the protection of pregnant women exposed to rubella. An analysis of results obtained during the period 1954–61 showed a reduction in the attack rates, but the more important question of whether congenital defects were also prevented could not be examined at that time (McDonald, 1963). Since then the isolation of rubella virus and the development of serological tests for antibody have enabled many aspects of the problem to be investigated with more precision. In a study of the effects of gammaglobulin on artificially induced rubella in volunteers Green *et al.* (1964) showed that serological conversion and viraemia may occur in the absence of clinical manifestations of illness. Brody *et al.* (1965) concluded from a trial among young schoolboys during an epidemic in Alaska that gammaglobulin halved the infection rate as determined serologically and reduced the clinical attack rate to about a quarter. The dosage used in this trial was relatively large—0.25 ml./lb. (0.55 ml./kg.) of body weight, presumably in 16% solution.

None of these findings is of much assistance to the pregnant woman or her doctor since they are compatible with optimistic and pessimistic interpretations. Quite modest doses of gammaglobulin may not only reduce risk of infection and clinical illness in the mother but protect the foetus should these occur; moreover, gammaglobulin might protect the foetus from other teratogenic agents. On the other hand, it has been argued that gammaglobulin may at most obscure the symptoms of rubella and do nothing to prevent viraemia or damage to the foetus, so giving rise to a false sense of security, which is worse than useless. This paper, which is mainly concerned with the outcome of pregnancy in women who have received gammaglobulin, throws some light on these questions.

Background

Between 1954 and the end of 1962 gammaglobulin was issued for 36,577 rubella contacts. The demand at first grew slowly, but an epidemic in 1958 helped to popularize its use, which thereafter was maintained at a higher level. Even so, by the end of 1960 only 9,556 doses had been issued, mostly during times of low prevalence. In 1961 the demand increased and 6,565 doses were issued; this was followed in 1962 by what appeared to be a severe and widespread epidemic (Fry *et al.*, 1962), during which 20,456 doses were distributed. The study reported in this paper is confined to the period 1956–62, during which 35,825 doses were issued.

Dosage and the types of gammaglobulin available underwent changes during the period of study. Until June 1958 the dose supplied was 750 mg., the same as that for measles; it was then increased arbitrarily to 1,500 mg., only to be reduced again to 750 mg. from June to September 1961 because of shortage. From then on 750 mg. remained the standard dose, though 1,500 mg. was supplied when the risk seemed specially high—for example, for home contacts exposed during the first eight weeks of pregnancy. As over 60 laboratories undertook the distribution of gammaglobulin and requests were considered on their merits, these trends give only a general indication of what occurred. Comparisons of the effects of dosage are therefore difficult and must be interpreted with caution.

Until 1961 all the gammaglobulin used was prepared at the Lister Institute and over half (54%) of the material used in the entire period was from that source, but after 1960 supplementation became necessary. In 1961 20% was from France, and in 1962 67% was from Holland and 9% from France. Lister gammaglobulin was prepared by the method of Kekwick and Mackay (1954) whereas the French and Dutch manufacturers used the Cohn *et al.* (1944) method of fractionation.

Methods

Information on whether or not women contracted rubella and on the outcome of pregnancy were obtained by three postal inquiries with standard questionary forms. The first inquiry was sent out with the gammaglobulin requesting the doctor to complete and return the form 28 days after inoculation. This form was returned for 30,764 (86%) of the doses issued during 1956–62. A substantial proportion of the remaining 14% of doses were sent back to the issuing laboratory unused; our record system did not allow for this, and the number so returned is unknown. The second inquiry, made three to nine months after the expected date of delivery, gave information on the pregnancy and the state of the baby at birth. It also confirmed whether or not rubella had occurred within 28 days of the injection or at any time subsequently. Of 30,764 forms sent out, 26,930 (88%) were returned. This form was also sent in respect of 143 women who were given gammaglobulin after the appearance of the rash in the hope of modifying the effects on the foetus; all these forms were completed.

Finally, when the children were at least 2 years of age a third postal inquiry was made about cases in which the foetus had been at greatest risk. This group comprised women known to have had rubella while pregnant, together with those who were in contact in the family during the first 12 weeks of gestation. In this inquiry the doctors were asked specifically about the presence of rubella-type defects—deafness, heart

* Epidemiological Research Laboratory, Colindale, London N.W.9.
† Present address: Department of Epidemiology and Health, McGill University, Montreal 2.

disease, and cataract. The third inquiry was sent in respect of 7,631 surviving children in the group at high risk and a report was received on 5,722 (75%). Most of the failures were due to the fact that the child's family had moved to a new address and could not be traced.

In addition to the three postal inquiries, 229 children whose mothers had rubella in pregnancy were selected from 360 children in this category who were reported alive at the second postnatal inquiry. The basis for selection was their proximity to a number of centres throughout the country to which they were called to be seen by one of us (C. S. P.). A complete physical examination was made with careful auditory and ophthalmic assessment; an electrocardiogram and chest *x*-ray film were taken when indicated. The Stycar test devised by Mary Sheridan (1958) was used for the detection of hearing defect.

Some of the least satisfactory data used in the analysis concerned the stage in pregnancy when the gammaglobulin was given. This question was not asked until the first postnatal inquiry, and by that time the doctor was often unable to supply the date of the last menstrual period. So far as possible the dates in question were estimated from available information and at worst from the date of delivery, but even this was not possible in pregnancies which ended in miscarriage.

Results

Rubella Attack Rate

Of the 30,764 women for whom there was information, 370 (1.2%) developed rubella within 28 days of inoculation and a further 97 (0.3%) at varying intervals thereafter. Table I shows that the attack rate was four times higher when the exposure to infection was in the family rather than elsewhere. Only before 1961 was there any evidence of better results with the higher dose. The attack rates increased about twofold between the early years and 1962. The reason for the increase was the high rate during the epidemic period in the first half of 1962 (Table II). The proportion attacked was highest in those given gammaglobulin immediately after exposure (Table III), but it is quite possible that those treated early were at greater risk. The distribution of intervals between exposure and onset of rubella when prophylaxis failed (see Chart) supports the accuracy of diagnosis in these cases. Unfortunately, it does not follow that when prophylaxis was apparently successful the diagnosis of illness in the primary case was equally accurate. Full analysis did not show any consistent difference between the results obtained with the Lister, Dutch, and French products and they have therefore been pooled. Detailed study showed that the attack rates in older women tended to be slightly higher than in younger women, but once again they may not have been at equal risk.

TABLE I.—*Rubella Attack Rates in Relation to Dose of Gammaglobulin and Type of Contact,* 1956–62

Years	Dose (mg.)	Type of Contact			
		In Family		Outside Family	
		No. at Risk	Attacked within 28 Days of Exposure No. (%)	No. at Risk	Attacked within 28 Days of Exposure No. (%)
1956–60	750	1,695	20 (1·18)	1,744	5 (0·29)
	1,500	2,119	17 (0·80)	2,273	5 (0·22)
1961	750	1,114	13 (1·17)	1,137	3 (0·26)
	1,500	1,516	27 (1·78)	1,821	5 (0·27)
1962	750	7,730	195 (2·52)	6,876	42 (0·61)
	1,500	999	24 (2·40)	1,288	13 (1·01)
1956–62	750	10,539	228 (2·16)	9,757	50 (0·51)
	1,500	4,634	68 (1·47)	5,382	23 (0·43)
All*		15,173	296 (1·95)	15,139	73 (0·48)

* In addition to the 30,312 women shown in this Table, there were 452 others for whom the type of contact or dose was not recorded; one of them developed rubella, making 370 cases in all. A further 97 women developed rubella more than 28 days after exposure.

TABLE II.—*Rubella Attack Rates in Family Contacts by Date of Inoculation,* 1956–62

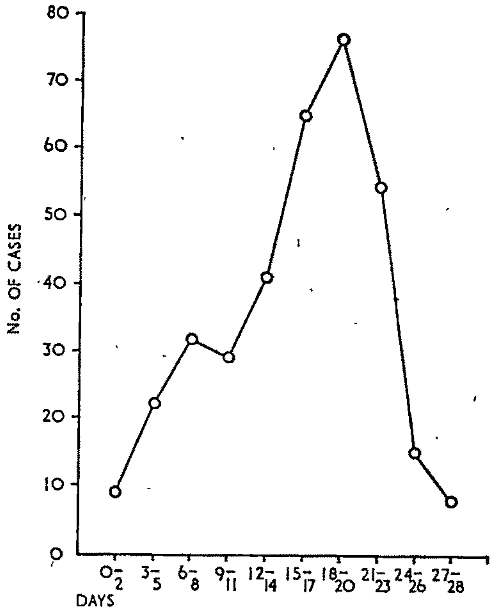
Season	1956–60		1961		1962	
	No. at Risk	Attacked No. (%)	No. at Risk	Attacked No. (%)	No. at Risk	Attacked No. (%)
Jan.–Mar. ..	Not known		409	7 (1·71)	1,598	40 (2·50)
Apr.–June ..			945	15 (1·59)	4,489	146 (3·25)
July–Sept. ..			837	11 (1·31)	2,068	29 (1·40)
Oct.–Dec. ..			441	7 (1·59)	584	4 (0·68)
Whole year(s) ..	3,816	37 (0·97%)	2,632	40 (1·52)	8,739	219 (2·51)

The figures in this Table do not agree entirely with those in Table I because information was not complete in all cases.

TABLE III.—*Rubella Attack Rates in Family Contacts in Relation to Time Between Exposure and Inoculation*

Year	No. at Risk	Exposure to Inoculation (Days)					
		0–4		5–12		13+ and Not Known	
		No. at Risk	Attacked No. (%)	No. at Risk	Attacked No. (%)	No. at Risk	Attacked No. (%)
1956–60	3,816	2,414	34 (1·4)	923	3 (0·3)	479	0
1961	2,632	1,713	31 (1·8)	577	5 (0·9)	342	4 (1·2)
1962	8,739	5,271	158 (3·0)	2,040	46 (2·2)	1,428	15 (1·0)
1956–62	15,187	9,398	223 (2·4)	3,540	54 (1·5)	2,249	19 (0·8)

The figures in this Table do not agree entirely with those in Table I because information was not complete in all cases.



Frequency distribution of intervals from exposure to onset of rubella in 351 cases (97 intervals of more than 28 days and 19 of uncertain length not shown).

Women with Rubella

Only 70% of the 610 women who had rubella in pregnancy came to term. In 16% pregnancy was terminated and the remainder either miscarried or were thought subsequently not to have been pregnant (Table IV). It may be seen in Table V that 13% of the children, live-born or stillborn, were reported to have congenital defects, and in the light of the additional findings in the sample of children visited 18% is probably a better estimate. This high figure was largely accounted for by deafness and heart defects, both characteristic of rubella. There were no cases of cataract, but in only 57 (13%) of 424 pregnancies known to have gone to term was the rubella in the first eight weeks of gestation.

The congenital defects present in this series are listed in Table VI according to the stage in pregnancy that rubella occurred and the stage of the inquiry at which they were ascertained. Most of the heart disease but little deafness was discovered at the first postnatal inquiry. The detailed examinations made during the visits after the second postnatal inquiry almost doubled the estimated percentage of deafness, but the additional cases were not severe and no other congenital defects were discovered at this time. About a quarter of the children whose mothers had rubella in the first 12 weeks had heart or hearing defects ; the rate fell to about 10% during the next four weeks and to about 5% after the sixteenth week. It is difficult to state these risks precisely because of the changing denominators at the first and second postnatal inquiries and visit. The outcome was more favourable in pregnancies in which rubella developed in spite of gammaglobulin than in those in which it was given after onset—4.8% compared with 2.2% for stillbirths and 12.4% compared with 8.2% for rubella-type defects—but these differences have little statistical significance (P>0.2 for both).

TABLE IV.—*Foetal Survival in Women with Rubella in Pregnancy,* 1956–62

	No of Cases of Rubella	Untraced at First Postnatal Inquiry	Not Pregnant	Surgical Abortion	Miscarriage	Total Births (Live and Still)	Stillbirths	Stillbirth Rate
Failures of prophylaxis	467	7	33	81	31	319	7	2·2%
Mother treated with gammaglobulin for rubella	143	0	3	17	18	105	5	4·8%
All cases	610	7 (1%)	36 (6%)	98 (16%)	49 (8%)	424 (70%)	12	2·8%

Except for stillbirth rates, percentages are calculated as a proportion of the number of cases of rubella; the figures for births include twins.

Women without Rubella

Information was obtained on the outcome of pregnancy in all but 13% of the 30,297 women who were in contact with rubella but escaped the illness. This information is summarized in Tables VII and VIII. Six per cent. aborted, 3% were thought subsequently not to have been pregnant, and the remainder gave birth to 23,931 children of which 381 (1.6%) were stillborn and 2.6% were stated to have congenital defects at the first postnatal inquiry. Despite a greater risk from rubella the stillbirth and defect rates in the family contact group were lower, if anything, than in the group with contact outside the family. Using information from the second postnatal inquiry, we estimated that the defect rate at this stage for children whose mothers had been exposed to rubella in the first 12 weeks of pregnancy was 3.6%. Of this total rate only 3.0 per thousand had hearing defects and 3.8 per thousand congenital heart disease.

TABLE V.—*Defects in Children of Women With Rubella in Pregnancy,* 1956–62

	No. of Live Births or Stillbirths at First Postnatal Inquiry	Live Births Untraced at Second Postnatal Inquiry	Children with Rubella-type Defects				Other Children with Defects	Total Children with Defects
			Deafness	Heart	Cataract	Any

	Pyloric stenosis ..	1				1

Defects are listed according to the stage of the inquiry that they were ascertained. Thus, for example, of the three children shown with heart defects and deafness whose mothers had rubella in the first eight weeks of pregnancy, by the second inquiry a heart defect had been noted in all of them, but only one was thought to have a hearing defect. At the visit the other two children were also found to have hearing defects.

TABLE VII.—*Foetal Survival in Women Who Were in Contact with Rubella in Pregnancy But Did Not Develop the Disease,* 1956–62

	No. of Women Inoculated who Did Not Develop Rubella	Untraced at First Postnatal Inquiry	Not Pregnant	Surgical Abortion	Miscarriage	Total Births	Stillbirths	
							No.	Rate
Family contacts	14,840	1,800	538	17	956	11,678	200	1·7%
Other contacts ..	15,032	1,836	397	5	866	12,055	177	1·5%
Contact not known	425	191	10	2	27	198	4	2·0%
All contacts ..	30,297	3,827 (13%)	945 (3%)	24 —	1,849 (6%)	23,931 (79%)	381	1·6%

Except for stillbirth rates, percentages are calculated as a proportion of the number inoculated; the figures for births include twins.

The possibility that gammaglobulin might protect the foetus from hazards other than rubella was also examined by means of data from the first postnatal inquiry. For embryological reasons the probability of any such effect would be greater the earlier in pregnancy the inoculation was given. In Table IX the outcome is analysed in relation to dose of gammaglobulin

TABLE VIII.—*Defects in Children of Women Who Were in Contact With Rubella But Did Not Develop the Disease,* 1956–62

Type of Contact	No. of Live Births and Stillbirths at First Postnatal Inquiry	Children with Rubella-type Defects				Other Children with Defects	All Children with Defects

and to whether it was given before or after the twelfth week. In terms of age distribution and type of rubella contact the four groups were closely comparable. The stillbirth rates were somewhat lower when gammaglobulin was given early, particularly in the higher dose ($P<0.05$). The defect rates also showed differences ($P<0.1$), but these seemed more closely related to dose than to time, and the pattern was not confined to any particular diagnostic groups. The analysis was carried through to a detailed consideration of over 80 specific defects; but wide variations, presumably due to chance, in even the more numerous categories, made the interpretation impossible. Frequencies for the main types of defect found at the first postnatal inquiry are set out in Table X for comparison with other surveys and as an indication of the level of case-finding achieved in this one.

TABLE X.—*Frequency of Congenital Defects Found At or Soon After Birth in* 23,931 *Live-born or Stillborn Children of Women Who Did Not Develop Rubella,* 1956–62

System	More Frequent Defects	No. (Rate/1,000)	Less Frequent Defects

The figures shown give the number of children with the specified defect whether or not other defects were also present.

Discussion

The two questions which require an answer are: does gammaglobulin reduce the attack rate in pregnant women exposed to rubella and, if so, is her child also protected. An attack rate of 1.95% in over 15,000 women, most of whom had no past history of rubella and who were in close contact with a case in the family, usually their own child, seems a low figure, but it is difficult to estimate accurately what it would have been without gammaglobulin. In an earlier report (McDonald, 1963) based on experience before 1962 the attack rate in family contacts was 1.27%, which compared favourably with a rate of at least 3.7% for untreated women in a survey carried out by the College of General Practitioners during roughly the same period (Watson and McDonald, 1963). In 1962, however, the attack rate rose to 2.5% in treated women and to 3.25% at the height of the epidemic. A family survey might have shown a similar increase in the rates for untreated women, but there is little information on this point.

In a description by Fry *et al.* (1962) of the 1962 epidemic in a large London suburban practice about 5% of all women of child-bearing age were actually seen with rubella, and it was estimated that the true attack rate was probably half as great again. Fry (personal communication, 1966) reported that in 156 families with a case of rubella 250 women aged 17–44 were at risk and 39 (15.6%) developed the disease. The figures are quite similar to those presented by Sever *et al.* (1965) for the 1964 epidemic in the U.S.A. They reported an attack rate of 3.5% in women exposed to rubella and given gammaglobulin (15–20 ml.) compared with 12.8% for unprotected women. The evidence from controlled trials must also be taken into account. Though these have been in children and not wholly consistent (Korns, 1952), results have generally indicated a substantial degree of protection (Landon *et al.*, 1949; Grayston and Watten, 1959; McDonald, 1963; Brody *et al.*, 1965). Altogether it seems very probable that without gammaglobulin the attack rate in pregnant women would have been substantially higher than it was.

The absence of an excess of rubella-type defects in the children of women who escaped rubella is more certain. The estimated rates per thousand for the children of family contacts in the first 12 weeks of pregnancy—deafness 3.0, heart defects 3.8, and cataract 0—seem to be within normal limits. Comparable figures, as yet unpublished, from a large prospective study of some 12,000 pregnancies conducted in Britain during the same period and using fairly similar methods of ascertainment were as follows: deafness 1.2, heart defects 4.5, and cataract 0.1. The rate for deafness was thus higher than in the normal series, but in our inquiry special emphasis was put on its detection. An additional point concerns the proportion of children with congenital heart disease who had a patent ductus arteriosus. This lesion is characteristic of rubella (Campbell, 1961), and in our series of women who contracted rubella 8 out of 13 children with heart disease had this defect. In contrast, in our series of women who escaped rubella there were only 11 cases of patent ductus in 93 cases of heart disease. These and other similar figures set out in Table XI suggest that if apparent rubella virus infections occurred they did no appreciable harm to the child.

TABLE XI.—*Patent Ductus Arteriosus as a Proportion of All Congenital Heart Disease*

Series	Description	Congenital Heart Disease		Patent Ductus Arteriosus	
		Rate/ 1,000 Births	No. of Cases	No. of Cases	% of Total
Current series ..	Rubella in early pregnancy	30·7	13	8	62
Manson *et al.* (1960)	Rubella in early pregnancy	26·4	15	Not stated	
Campbell (1961) ..	Congenital heart disease after maternal rubella		153	89	58
McDonald (1961)	Prospective inquiry in normal women	4·7	15	1	7
Slater *et al.* (1964)	Notified cases from general practice		About 1,282	153	12
McDonald (1966)	Prospective inquiry in normal women	4·5	50	12	24
Current series	Rubella contact in family	4·4	44	3	7
	Rubella contact outside family	4·1	49	8	16

Summary

Reports were obtained on the result of inoculation of 30,764 women with gammaglobulin after exposure to rubella in pregnancy during the years 1956–62. The outcome was ascertained soon after the expected date of delivery in 26,930 (88%) cases, and further inquiries were made on selected samples of surviving children when they were 2 or more years of age.

In 1.95% of family contacts and 0.48% of contacts outside the family clinical signs of rubella developed within 28 days of inoculation. Without gammaglobulin these rates would probably have been substantially higher.

Of 610 women who had rubella in pregnancy only 70% came to term. About a quarter of the children whose mothers had the disease in the first 12 weeks had heart or hearing defects; the proportion fell to about 10% for the next four weeks and then to about 5%. The rates for stillbirth and for rubella-type defects were higher when gammaglobulin had been given *after* the onset of rubella than when the disease developed despite prophylaxis, but these differences could have been by chance ($P>0.2$).

There was no excess of cataract or heart disease and probably no excess of deafness in the children of women who did not develop rubella though exposed to it. Subclinical rubella virus infection either carried little risk for the foetus or did not occur often enough for any adverse effect to be detected.

A lower proportion of children whose mothers received gammaglobulin in the first 12 weeks of pregnancy were stillborn (1.3% compared with 1.7%; $P<0.05$) or had congenital defects (2.4% compared with 2.9%; $P<0.1$) than of those whose mothers were injected after the twelfth week.

We are indebted to many people for their help in this inquiry, in particular to general practitioners throughout the country who dealt patiently with our repeated requests for information, and to Miss Barbara Kinsley and Mrs. G. V. Smith for their work on the analysis. The investigation was carried out in the Public Health Laboratory Service assisted by a grant from the Medical Research Council.

Incidence of Rubella Antibodies among Pregnant Women in Six Areas: Prophylactic Effect of Two Doses of Gammaglobulin

Report* to the Public Health Laboratory Service Rubella Working Party

Brit. med. J., 1967, **3**, 638–640

The use of gammaglobulin as a prophylactic in pregnant women exposed to rubella during the first trimester has been accepted practice for over a decade. Several surveys have been made to assess its efficacy, but the results showed little agreement (Lundström, 1965). With the isolation of the rubella virus (Parkman *et al.*, 1962 ; Weller and Neva, 1962) an accurate assessment of the value of gammaglobulin as a prophylactic was to be expected. However, the results of experimental work (Green *et al.*, 1964) indicated that gammaglobulin was not protective, whereas field trials (Brody *et al.*, 1965) suggested that some protection was afforded.

During the past 18 months studies into gammaglobulin prophylaxis in pregnant women exposed to rubella have been conducted in this laboratory. This communication reports some of the results so far obtained in two surveys using different dose schedules and the incidence of rubella antibodies in pregnant women in different areas of England.

Method of Study

In England and Wales general practitioners requiring gammaglobulin obtain their supplies from public health laboratories which serve as distribution centres. During the period of both studies an initial dose of 750–800 mg. of gammaglobulin was supplied for each pregnant woman exposed to rubella in the first 16 weeks of pregnancy. Gammaglobulin of both English and Dutch manufacture was used, and several different batches of each product were distributed.

The first study (Study A) was conducted from April 1965 to March 1966 in the area served by the Manchester Public Health Laboratory. Before giving gammaglobulin to patients exposed to rubella in the resident family (home contact) general practitioners collected a specimen of the patient's blood and sent it to the laboratory by post. Each serum was examined for the presence of rubella-neutralizing antibody within a week of receipt. Approximately six weeks later a second specimen was obtained from all these patients whether initially with or without antibody, and the paired sera were titrated together. As only a small percentage of Manchester women were found to be non-immune and as a single dose of 750 mg. of gammaglobulin did not prevent infection in some of these patients, a second study (Study B) was begun in March 1966. The investigation was extended in order to study a large number of non-immunes and to assess the value of a larger dose of gammaglobulin. This report records the results obtained up to 31 August 1966.

General practitioners receiving supplies of gammaglobulin from six public health laboratories for patients exposed both at home and elsewhere (other contracts) collected a specimen of whole blood from their patients and sent these specimens direct to the Manchester laboratory by post. Where possible a throat swab was collected for virus isolation from the suspected case of rubella and posted to the laboratory. The sera were examined for rubella-neutralizing antibody within 48 hours of receipt, the results being available within four days of setting up the test.

If neutralizing antibody was not detected or found to be present at a titre no greater than 1/4 the patient was, for the purposes of this investigation, regarded as non-immune and the local public health laboratory sent a further 1,500 mg. of gammaglobulin to the practitioner to be given to his patient if she was still within 12 days of contact. In home contacts the day of appearance of the rash was taken as the day of contact. Six weeks after the initial dose of gammaglobulin a second specimen of blood was obtained from these patients.

Materials and Methods

Sera.—Blood obtained from the patients was separated and sera were stored at −20° C. and were not inactivated.

Neutralization Tests.—These were performed in the RK.13 continuous line of rabbit kidney cells (Beale *et al.*, 1963). The propagation of the cells and the technique of the neutralization test are described in detail elsewhere (Hutchinson and Thompson, 1965).

Dilutions of sera were prepared in 0.3-ml. amounts to which were added an equal volume of rubella virus suspension ("West Point" strain) diluted to contain 1,000 T.C.D.$_{50}$ per ml. After incubation at 37° C. for one hour an inoculum of 0.2 ml. was added to each of two tubes of RK.13 cells containing 0.8 ml. of medium. Control sera and virus titrations were incorporated in each batch of tests. On receipt, sera were examined for the presence of rubella-neutralizing antibody at serum dilutions of 1/2 and 1/8 only. Titrations were performed with fourfold serum dilutions in the range 1/2 to 1/128. The titre was reported as that dilution of serum inoculated into tubes showing an unequivocal reduction in the number of microfoci, and not, as previously, the dilution of serum in the serum-virus mixture (Hutchinson and Thompson, 1965).

Results

Study A.—Of 429 sera obtained from pregnant women who had home contacts in the Manchester area in 1965–6, only

TABLE I.—*Examination of Paired Sera from Non-immunes*

Study	Amount of Gammaglobulin Given	Total No. Pairs Examined	No. of 2nd* Sera with Neutralizing Antibody	% Infected
		Home Contacts

* The Public Health Laboratory Service consultants assisting in the investigations were Dr. B. W. Barton (Derby), Dr. W. L. Hooper (Stafford), Dr. Hélène J. Mair and Dr. N. S. Mair (Leicester), Dr. J. H. McCoy (Hull), Dr. Pauline M. Poole (Chester), and Dr. J. O'H. Tobin (Manchester). The tests were carried out at the Manchester laboratory by Mrs. Eileen Smith, Mr. K. M. Thompson, and Dr. D. N. Hutchinson. The report was prepared by Dr. D. N. Hutchinson.

21 (4.9%) did not possess rubella-neutralizing antibody. A second serum was obtained from 20 of these 21 negatives and the results of examination of these 20 pairs are given in Table I. Six of these patients had developed neutralizing antibody by the time the second specimen was collected. Four of the patients were known to have had clinical rubella, and rubella virus was isolated from the throat in each case.

Study B.—The results of the examination of 1,326 sera obtained from all contacts of rubella in the areas served by the six public health laboratories are shown in Table II. The proportion of non-immunes varied from 21% to 6.3%. The results obtained on examination of pairs of sera from 39 non-immune home contacts and 69 other non-immune contacts are shown in Table I. Six of the 12 women who had developed neutralizing antibody in the second specimen were reported as having had clinical rubella. Rubella virus was isolated from the throat of the two patients from whom specimens were received. Sixteen patients were reported as having a neutralizing antibody titre of 1/4 in the first serum specimen. Titration of paired sera from the patients showed that one pair contained no antibody, five pairs had a titre of 1/8, and the other 10 pairs remained unchanged at a titre of 1/4. In non-immune family contacts the mean number of days between contact and the first dose of gammaglobulin was 4.8 days in those receiving one dose and 2.8 days in those receiving two doses. In the non-family contacts the mean was 7.4 days for those receiving one dose and 5.0 days for those receiving two doses.

TABLE II.—*Rubella-neutralizing Antibody Among Pregnant Women Exposed to Rubella in Sera from Areas Served by Six Public Health Laboratories*

Public Health Laboratory	No. of Sera Examined	Negative*		Contact History*					
				Family			Other		
				Total	Negative		Total	Negative	
		No.	%		No.	%		No.	%
Chester ..	84	11	13·1	28	2	7·1	53	9	17·0

Total	1,326	134	10·1	488	41	8·4	781	91	11·7

* Excludes those patients with a titre of 1/4 or where the contact history was not known.

Discussion

Workers in America (Sever *et al.*, 1965b) Canada (Givan *et al.*, 1965) and Sweden (A. Svedmyr, personal communication, 1966) have reported that 80 to 90% of women of child-bearing age possess rubella-neutralizing antibody. Dudgeon *et al.* (1964), in this country, found rubella-neutralizing antibody in 82% of cord bloods obtained from a London hospital. In the areas served by the six laboratories we have found a marked variation in the number of immunes, the proportion ranging from 80 to 94%. These differences are possibly associated with the differing size of industrial, urban, and rural populations which these laboratories serve. Our findings are similar to those of Sever *et al.* (1964), who examined sera from several centres in the U.S.A. and found a large difference in the number of immunes between areas and ethnic groups. This variation in different areas makes assessment of field trials into the protective effect of gammaglobulin unreliable, unless the immune state of each area being studied is known.

In five areas the percentage of susceptibles in home contacts was less than that for the other contact group. The total number of patients examined, so far, is too small to attach significance to this finding.

Of 30 non-immune home contacts from both studies who were given only one dose (750–800 mg.) of gammaglobulin, 26.7% showed evidence of infection (Table I). In Study B, 29 home contacts were given an additional dose (1,500 mg.) of gammaglobulin between 8 and 12 days after contact. Of these, 31% were infected. All but one of the patients showing evidence of infection received the initial dose of gammaglobulin within three days of contact. However, the results do not indicate that the giving of a second dose late in the incubation period increases the maternal protection to infection (McDonald, 1963).

The risk of maternal infection would not appear to be very great when the patient and the contact were not living in the same house. Only one of 69 such non-immune contacts (51 given a second dose of gammaglobulin) developed evidence of rubella infection. This patient had repeated contact with several children while transporting them to and from school. Her own child did not develop clinical rubella.

In a review of the protection afforded by gammaglobulin, Lundström (1965) tabulated the results of various surveys and trials and drew attention to the widely different attack rates obtained. Sever *et al.* (1965a), in a preliminary report on the prophylactic value of gammaglobulin given to pregnant women in the first trimester, found a significant reduction in clinical rubella occurring within one month after exposure. It is not yet possible to assess their results as serological data were available for only a small number of cases. McDonald (1963), in this country, found that 1.27% of home contacts who received gammaglobulin still developed clinical rubella. In our studies attack rates of 0.93% (A) and 1.02% (B) were found in all home contacts. However, the true attack rate in susceptible home contacts is at least 30%.

Sixteen batches of gammaglobulin used during these studies were titrated for neutralizing antibody. The titres ranged from 1/32 to 1/256. In our studies too few susceptibles have received material from any one batch to detect a significant difference. Korns (1952) found that only one of three batches of gammaglobulin gave significant protection in field trials. On testing 17 different batches of gammaglobulin, Schiff *et al.* (1963) found an eightfold difference in titres, and they concluded that the variation in the protective value of different lots of gammaglobulin was a reflection of this titre difference. In future trials the titre of rubella-neutralizing antibody in the different batches of gammaglobulin issued should be known and preferably only those with a high titre used.

An attempt was made during study B to prove that the patient was exposed to rubella, as several enteroviruses are known to produce a rubelliform rash (Lerner *et al.*, 1963). A throat swab was obtained from the index cases of home contacts, but this usually necessitated a special visit by the practitioner or a member of the laboratory staff, and was not always possible. Nine specimens collected within four days of the rash were received from children of non-immune home contacts. Rubella virus was isolated from the child of a patient who developed neutralizing antibody. In the other eight instances virus was not isolated and the patients remained non-immune. From other studies in patients with serological proof of rubella infection a virus isolation rate of 90% could be expected from throat swabs transported overnight in the post—a similar result to that obtained by early inoculation of cultures (to be published).

These studies indicate that it is necessary to investigate the prophylactic effect of giving a large dose of gammaglobulin as soon as possible after contact. To do so would be costly, and in future trials some saving would be effected by restricting the use of the large dose to home contacts. If a more rapid test for the detection of rubella antibody was available greater economy could be made. So far, fluorescent antibody techniques (Brown *et al.*, 1964) have not proved readily adaptable to the testing of large numbers of sera; however, a haemagglutination inhibition test for the detection of rubella antibodies may prove suitable for this purpose (Stewart *et al.*, 1967).

This report records only the effect of gammaglobulin on maternal infection, and it is possible that the administration of gammaglobulin, though not preventing maternal rubella, may still reduce the frequency and the severity of foetal abnormalities. It is hoped to study the outcome of the pregnancies in the susceptible patients.

Summary

In six areas of England and Wales the incidence of rubella-neutralizing antibody among pregnant women exposed was found to vary from 80 to 95%.

Two different dose schedules were used and the prophylactic effect of gammaglobulin in pregnant rubella contacts was investigated. The attack rate in home contacts given 750 mg. of gammaglobulin was 26.7%. In similar contacts given an initial dose of 750 mg. followed by a further 1,500 mg. within 12 days of exposure the attack rate was 31%. In non-family contacts only one out of 69 susceptibles developed evidence of rubella infection.

It is a pleasure to record the co-operation of the many general practitioners in the areas served by the six public health laboratories; these investigations would not have been possible without their assistance. This work was supported by a research grant from the Ministry of Health to the P.H.L.S. Rubella Working Party. The members of the Working Party are: Dr. A. D. Macrae (Colindale) (chairman), Dr. D. Reid (Colindale) (secretary), Dr. C. M. P. Bradstreet (Colindale), Dr. S. K. R. Clarke (Bristol), Miss A. M. Field (Colindale), Dr. J. H. Hale (Newcastle upon Tyne), Dr. M. H. Hambling (Leeds), Dr. D. N. Hutchinson (Manchester), Dr. W. F. Lane (Bedford), Dr. C. Miller (Medical Research Council Laboratories, Hampstead), Mr. J. Pope (Colindale), Dr. G. B. B. White (Liverpool), and Dr. J. E. M. Whitehead (Coventry).

Comparison of Intragastric and Intravenous Routes of Glucose/Bicarbonate Administration in Respiratory Distress Syndrome

J. M. ABRAHAM,* M.B., B.S., M.R.C.P., M.R.C.P.ED., M.R.C.P.GLASG., D.C.H.; R. J. K. BROWN,† M.B., F.R.C.P., D.C.H.

Brit. med. J., 1967, **3**, 640–642

After the reports of Usher (1959, 1961), who suggested that the use of glucose/sodium bicarbonate solutions had led to a significant reduction in the mortality from the respiratory distress syndrome, his form of treatment was given a preliminary trial in the neonatal ward at the Queen Elizabeth Hospital for Children during 1961 and 1962. Among 61 infants treated within 24 hours of birth with *intravenous* therapy according to his suggested dosage there were 18 deaths, a mortality of 29.5%. Usher emphasized the need to start the infusion early, preferably within three hours, if it was to have any demonstrable effect on the survival rate. Our experience confirmed this, for among 10 babies whose treatment was delayed for over 24 hours there were nine deaths. If these babies had been included in our preliminary trial there would have been 27 deaths out of a total of 71 babies and the mortality increased to 38%. It would, however, give a fairer estimate of the mortality if the 10 cases in which treatment had been delayed for 24 hours or more were excluded. However, even the figure of 38% is significantly lower than the average 60% mortality in most previously reported series where bicarbonate had not been administered.

Unfortunately, in this hospital there were not enough controls to provide statistical proof that the treatment was of value, though there had been 32 babies who had received oxygen and increased humidity but no bicarbonate, and among these there were 17 deaths, a mortality of 53%. The results are given in Table I, alongside some results reported from Glasgow (Hutchison *et al.*, 1962).

TABLE I.—*Comparison of the Mortality Rates from R.D.S. With and Without Treatment With Intravenous Glucose/Sodium Bicarbonate Infusion in Two Centres*

Source	Q.E.H.C. (1961–2). Glucose/$NaHCO_3$ by I.V. Infusion				Glasgow (1962). Glucose and $NaHCO_3$ by "Titration"		Glasgow. O_2 and Humidified Air			
	I All Cases		II Omitting Cases Treated After 24 Hours				1960		1961	
	No.	%	No.	%	No.	%	No.	%	No.	%
Deaths	27*	38	18	29·5	11	41	48	66	38	64
Survivals ..	44	62	43	70·5	16	59	25	34	21	36
Total ..	71		61		27		73		59	

* Nine of these deaths occurred among 10 cases that did not start therapy until 24 hours or more had elapsed, thus causing the mortality to be increased by nearly 10% more than need be.

Differences between percentage mortality rates in the two Glasgow series (results for 1960 and 1961 combined) $P < 0{\cdot}02$ (this is "significant").

The Glasgow figures are quoted from Hutchison *et al.* (1962).

* Lately Medical Registrar, Queen Elizabeth Hospital for Children, London E.2.

† Consultant Paediatrician, Queen Elizabeth Hospital for Children, London E.2.

Though lacking strict statistical proof, the results of our preliminary trial engendered a firm conviction that prompt treatment directed against a metabolic acidosis by means of infusions of glucose and sodium bicarbonate could reduce the mortality of the respiratory distress syndrome. With experience the team concerned in the management of these cases became skilled in setting up scalp-vein infusions. In spite of this, difficulties were often encountered which entailed too much handling of very ill infants. Once an intravenous infusion containing glucose has been started there is the risk of "hypoglycaemic shock" if the drip should stop. To avoid this the needle must be reinserted into another vein within an hour, often into an already oedematous scalp. For these reasons it did not seem feasible to use this treatment in the maternity units unless a simpler method of infusion could be used. Because of the dangers of phlebothrombosis it was thought inadvisable to use the umbilical vein.

It was decided, therefore, to carry out a trial in which alternate infants were given the solution intravenously and intragastrically.

Material and Method

Babies were referred from maternity units in affiliated hospitals, mostly within a few hours of delivery, on developing clinical signs of respiratory distress (R.D.S.). They were transported in portable incubators in oxygen (about 25% concentration at the nostril) without increased humidity and before any treatment was initiated. If on arrival they were thought to conform clinically to hyaline membrane disease (H.M.D.) they were allocated alternately to one of two ways of glucose/sodium bicarbonate administration, the one parenterally through a scalp-vein needle (I.V.), the other by gavage (I.G.). Otherwise management was identical for both groups, by the same staff.

The babies were nursed in humidified incubators, and oxygen was administered in a concentration which was thought by the ward sister to be sufficient to control their cyanosis. The usual percentage ranged between 40 and 60% at the nostril. The dosage of sodium bicarbonate in 10% dextrose solution (65 ml./kg./day) was regulated according to serial *p*H estimations of heel capillary blood (Usher, 1961). The solution was given as a slow continuous drip through a polyvynyl stomach tube. Insulin was never used. Antibiotics (penicillin 150,000 units and streptomycin 50 mg. b.d.) and on many occasions a synthetic pressor amine, mephentermine sulphate (1.25 mg. two-hourly when the patient was severely distressed), were administered. Severity of respiratory distress was judged clinically by the respiratory rate, the degree of cyanosis, and the Silverman retraction score (Silverman and Andersen, 1956). With the last, those scoring up to 5 were regarded as mild, 5–7 as moderate, and 8–10 as severe cases. The chest was radiographed on the first morning after admission. A radiograph showing an air bronchogram, a diffuse reticulogranular pattern, or both, was regarded as positive for hyaline membrane disease.

Results

Table II shows the scope of the trial. Of 120 patients who were provisionally given the diagnosis of hyaline membrane disease and started on the alternate treaments 21 were excluded, either because there was no confirmatory biochemical and radiological evidence of the disease and subsequent progress showed nothing more than minimal intercostal recession, or because an alternative diagnosis became obvious later. In retrospect it was apparent that sufficient care had not been taken to obviate bias in the selection of treatment for babies who happened to arrive on the ward simultaneously. Though these included four sets of twins, it was reluctantly decided that they should be excluded from the trial. Babies who were more than 24 hours old on arrival were also excluded, because the preliminary trial had shown that treatment did not influence the survival rate in this group (see Table I). Finally, it was necessary to exclude all those babies for whom the treatment had subsequently been changed for one reason or another.

TABLE II.—*Scope of Trial and Reasons for Exclusion of 73 Cases Referred Initially With Signs of Respiratory Distress*

Period of trial: May 1964–November 1965 (excluding June and July 1965 owing to temporary change of staff)				16 months
No. of cases referred as R.D.S...				152
Excluded:				
(1) Not H.M.D. on initial clinical examination ..			32	
(2) Not H.M.D. on retrospective analysis	15*	6†	21	
Symptoms insufficient for diagnosis of H.M.D. ..	8	3		
Pneumonia	4	1		
Urethral valve: severe metabolic acidosis	1	—		
Neonatal hypoglycaemia ..	—	1		
Congenital heart disease ..	1	—		
Cerebral irritation	1	1‡		
(3) Clinically H.M.D. but omitted for following reasons			20	
Twins (4 × 2)		8		
Arrived simultaneously (2 × 2) ..		4		
Change of treatment I.G. to I.V. ..		5		
Over 24 hours old on admission ..		3		73
No. of cases remaining in the trial				79

* Intragastric. † Intravenous. ‡ Died with intraventricular haemorrhage.

Of the remaining 79 cases 36 were in the "intragastric group" and 43 in the "intravenous group," with 8 and 17 deaths respectively (Table III). Of the 20 cases which finally came to necropsy 18 showed typical hyaline membranes, a reflection of the accuracy of the initial diagnosis.

TABLE III.—*Comparison of Mortality Rates of Two Groups of Alternate Intragastric and Intravenous Administration of Glucose and Sodium Bicarbonate Mixture, and Time When Milk Feeds Begun in Survivors*

	Total No.	Deaths	Time When Milk Feeds Begun
Intragastric	36	8 (22·2%)	67·9 (26–140) hours
Intravenous	43	17 (39·5%)	64·9 (22–115) ,,

Difference between mortality rates = 17·3%. S.E. of difference = 10 5 : 2 (S.E.) = 21. On χ^2 analysis, P = 0·10.

It was hoped that by alternate allocation the two groups would match. However, it will be seen that, though the mean values in many instances are comparable (Table IV), the distribution of some important criteria is not (see Chart). Even allowing for this the difference between the mortality rates is not statistically significant (P=0.10).

TABLE IV.—*Analysis of Clinical and Biochemical Data of 79 Subjects Included in Trial and the Necropsy Findings in 20 Cases*

	Whole Group		Deaths	
	I.G.	I.V.	I.G.	I.V.

Atelectasis			6	12
Intraventricular haemorrhage			1 (female)	6 (1 female)

Discussion

The results of this trial are capable of different interpretations. If one is sceptical of the value of this type of treatment it could be argued that it has done nothing to help these infants, and the difference between the survival rates in the two groups is entirely due to chance. Indeed, it could be suggested that infusing relatively large amounts of fluid and sodium bicarbonate into distressed premature babies is even positively harmful, but less so when the intragastric route is used, because of poor absorption from the alimentary tract, and hence the lower mortality in this group. Neither of these explanations is really acceptable. It is reasonable to expect that careful correction of a metabolic acidosis will benefit a sick infant as it does when acidosis results from other causes such as severe gastroenteritis.

WEIGHT (g.)		INITIAL pH OF HEEL CAPILLARY BLOOD	
>2500	△△△△ ●○○○○○○	>7·3-	△
2251-2500	▲▲△△△△△△△ ○○○○○○	7·2-7·3	▲▲▲△△△△△△△△△ ●○○○○○○○○○○
2001-2250	▲▲▲△△△△△ ○○○○○○	7·1-7·2	▲▲▲▲▲△△△△△△△△△△△△△△ ●●○○○○○○○○○○○○○○○
1751-2000	▲▲△△△△ ●○○○○○	7·0-7·1	▲▲▲▲ ●○○○

<1500	▲▲▲▲△△ ●●●●○○○○		

Intravenous. SURVIVAL △ DEATH ▲ Intragastric. SURVIVAL ○ DEATH ●

Distribution of birth weight and initial *p*H in the two groups.

The published results of several trials have all shown an appreciable reduction in the mortality from the respiratory distress syndrome when intravenous infusions of glucose/sodium bicarbonate have been administered (Usher, 1959, 1961, 1963 ; Hutchison *et al.*, 1962), and the preliminary trial of intravenous therapy in this hospital showed a definite improvement over other forms of therapy which had been used previously. Thus there is no good evidence that these infusions are harmful. The evidence of positive benefit is not quite so convincing, because it is to be expected that intensive care in special units will by itself result in an improved survival rate, but many people have been convinced of this by Usher's (1963) controlled trial.

If it is assumed that the infusion of glucose/sodium bicarbonate solutions is beneficial the results of the present trial show that it is just as effective when given by the intragastric route. In all the cases given intragastric therapy there was biochemical evidence that the bicarbonate was well absorbed and was able to correct the *p*H just as effectively as the intravenous bicarbonate (Table V). Though the mortality in the intravenous group is much greater than in the intragastric group, statistical analysis shows that this difference could have occurred by chance. However, it is remarkable that the intragastric group seems to fare better in consideration of nearly all criteria, and it may be that the greater degree of handling necessary for intravenous therapy is an important factor.

Absorption from the neonatal gut is facilitated by the presence of a well-developed mucosa, though its rate in the first few hours is uncertain. There has been evidence of good absorption of sodium bicarbonate from the gut of babies in this trial, not only from the satisfactory correction of an existing metabolic acidosis, but also from the considerable rise in the total bicarbonate in several cases.

TABLE V.—*Comparison of Biochemical Changes Produced by Intragastric and Intravenous Therapy*

	Baby V. Intravenous		Baby T. Intragastric	
	1	2	1	2
*p*H	7·12	7·39	7·04	7·31
P_{CO_2}	72·2	57	106	85
Base excess	−14·2	+6·3	−17·7	+9·7
Buffer base	41·1	55·8	38·9	59·0
Standard bicarbonate.. ..	15·1	29·3	13·6	31·7
Actual bicarbonate	23·8	33·0	28	41·0
Total CO_2	26·0	35·0	31	43·6

In each case, column 1 represents initial findings. Column 2 represents the findings after less than 24 hours' sodium bicarbonate therapy.

Administration of these infusions by the gastric route has obvious merits, and now that it has been shown that the results are as good as those obtained by intravenous therapy, if not better, it can be firmly recommended as the route of first choice. Rarely, resort has to be made to the intravenous route because of vomiting.

Summary

A clinical trial was carried out to compare the relative values of the intravenous and the intragastric routes for infusion of solutions of glucose and sodium bicarbonate in the management of babies with the respiratory distress syndrome. Somewhat surprisingly those babies who received their infusions intragastrically had a lower mortality rate. Though the difference between the mortality rates was not statistically significant, there is reason to believe that the intragastric route of administration should be preferred.

We are indebted to Sister B. S. Beech, who was in charge of the unit throughout the period of trial and played a helpful and active part in the management of the babies, and to Dr. S. H. Ng, who carried out a great deal of work involved in the preliminary trial. We are also grateful to Dr. R. H. Dobbs and Dr. A. D. M. Jackson for allowing us to include patients under their care, to Dr. B. Levin for the biochemical investigations, and Dr. N. E. France for the morbid anatomy and histology.

Formed Visual Hallucinations: a Symptom of Cranial Arteritis

C. T. HART,* M.B., B.S., F.R.C.S.

Brit. med. J., 1967, 3, 643–644

Two cases of cranial arteritis are described in which the presence of formed visual hallucinations has been a significant factor in their clinical presentation and course. The purpose of this paper is to draw attention to this symptom—not previously reported—and to suggest a possible aetiology in view of the known pathology of cranial arteritis. It is now well recognized that the disease process, a panarteritis, may involve not only the superficial temporal branches and other divisions of the external carotid but also the internal carotid tree, and the subclavian, coronary, renal, mesenteric, pulmonary, and peripheral vasculature. A full consideration of the pathology, incidence, and symptoms of cranial arteritis will not be dealt with in the present report, since these are well described in previous publications (Horton, Magath, and Brown, 1932; Parsons-Smith, 1959; Simmons and Cogan, 1962).

Case 1

A 79-year-old woman presented in the ophthalmic department on 17 March 1966 with deterioration of vision in the left eye of two weeks' duration. Clinical examination revealed atrophy of the left disc; arterial attenuation, no haemorrhages or exudates. The right disc showed early blurring of the nasal margin. Visual acuity: right, 6/18; left, counting fingers. B.P. was 180/80. Skull *x*-ray examination showed nothing abnormal. E.S.R. was 101 mm./hr.

Further questioning revealed a history of severe headaches associated with tenderness over the temples. She had been seen one month earlier at a dental hospital because of severe pain on chewing. Subsequently she referred to formed visual hallucinations of a most unpleasant nature which had been present for approximately two weeks before her ophthalmic attendance.

Prednisolone 30 mg. brought an immediate improvement in her general condition, and the visual hallucinations disappeared. Treatment was gradually reduced to nil on 25 July, when the E.S.R. was steady at 5 mm./hr. and she was symptom-free.

On 13 November she returned complaining of malaise and a recurrence of disturbing visual hallucinations. Visual acuity: right, 6/18; left, counting fingers. Central field right showed marked inferotemporal field loss with some generalized constriction. The right disc was now thought to be atrophic. B.P. was 160/70; serum vitamin B_{12}, 307 μg./100 ml.; and E.S.R. 82 mm./hr. Applanation pressures right and left, 20 mm.

A temporal artery biopsy was not thought necessary in view of the previous response to treatment, as regards both symptoms and the diminution in the E.S.R. Prednisolone 30 mg./day orally was begun with immediate loss of the formed hallucinations, which up to the time of writing had not recurred on a continued dosage of 5 mg. of prednisolone b.d.

Formed visual hallucinations preceded both emergency ophthalmic attendances. For two weeks before the first visit the patient experienced images of menacing people and flapping brightly coloured curtains which promptly disappeared as soon as systemic corticosteroid therapy was begun. The second visit after four months without corticosteroids was preceded by hallucinations of two days' duration; these took the form of doors which opened out towards her, the doors in fact being quite real; also the patient "saw" a crowd of small children round her whenever she turned her head to either side; treatment with corticosteroids abolished these hallucinations, which have not since returned. Improvement in visual acuity did not occur.

Case 2

A 73-year-old woman was admitted as a medical emergency on 19 February 1963 with bilateral severe visual loss and a diagnosis of possible intracranial space-occupying lesion. One week before admission she presented in the ophthalmic department with sudden loss of vision in the right eye of four days' duration. Papilloedema of the right disc was noticed at this first attendance. A blood pressure of 176/118 was found and she was referred for medical opinion, a hypertensive cause being suspected. The same day sudden loss of visual acuity in the left eye was experienced. On her admission to the ward a past history of three months' occipital headaches, bilateral earache, and jaw ache was obtained.

The clinical findings were as follows. Visual acuity: right, counting fingers; left, counting fingers; fields limited to superotemporal quadrants on confrontation; bilateral papilloedema, no haemorrhages or exudates; B.P. 170/76.

Investigations: E.S.R. 20 mm./hr. Serum cholesterol 310 mg./100 ml. Serum electrophoresis normal. Skull and chest *x*-ray pictures normal.

A diagnosis of cranial arteritis was made and temporal artery biopsy obtained which was reported on as follows: "There is an inflammatory reaction with giant cells in the vessel wall and the elastic tissue is partially disrupted: A 'kink' noted on naked-eye examination of the vessel shows filling of the lumen by organized thrombus which is beginning to recanalize."

The patient began treatment with 60 mg. of prednisolone a day. No improvement in visual acuity occurred. She has now terminated corticosteroid therapy. At no time has the E.S.R. exceeded a level of 20 mm./hr.

Formed visual hallucinations began three months after ocular involvement and have continued for four years. Originally these consisted of three distinct forms: (*a*) three blue and white meat dishes arranged vertically; (*b*) bunches of brightly coloured flowers situated on either shoulder, which swayed as she turned her head; and (*c*) black men outside the window. The first form of hallucination (*a*) persists, though the frequency of appearance has markedly decreased.

On examination on 23 March 1967 she was noted to have visual acuity: right, hand movements; left, hand movements; bilateral atrophic discs; applanation pressures right and left, 18 mm.

Discussion

The incidence of intracranial complications of cranial arteritis would appear to be small, judging from the lack of published evidence to the contrary. Meadows (1954) described the cases of two patients with dementia and one with progressive failure of memory for two years preceding the onset of blindness. Symptoms of vertigo, tinnitus, and loss of hearing have been described (Font, 1960) as occurring in this condition, the cause being presumed to be occlusive involvement of the internal auditory artery. Parsons-Smith (1959) described a series of 50 cases, four of which showed field loss (the type of field loss is not specified) due to cerebral lesions consistent with cranial arteritis.

The symptom of formed visual hallucinations experienced by the above two patients is assumed to be due to involvement of the cerebral cortex, particularly the temporal lobes, by this same occlusive vascular condition.

The onset and duration of the symptom vary greatly in the two cases. Case 1 demonstrated it as a premonitory symptom, associated initially with loss of unilateral vision and subsequently substantial loss of field in the unaffected eye, relieved by the administration of systemic corticosteroids: the hallucinations were a very temporary effect of cortical ischaemia relieved by prednisolone. In Case 2 the hallucinations occurred after an interval of two months, following severe bilateral loss of visual acuity, with no relief from corticosteroid therapy; in this particular case it must be assumed that the occlusive process has been permanent. The time of onset of this symptom after ocular involvement is of interest since it corroborates previous descriptions in that the generalized effect of cranial arteritis may follow ocular involvement by an interval of one to six months.

---

* Department of Ophthalmology, University of Sheffield.

The rarity of visual hallucinations in the blind has been noted by Freeman and Williams (1953) and it should be stressed at this stage that the formed hallucinations experienced by these two patients in no way resemble the psychic disturbances of postoperative cataract patients in which the imagery promptly disappears on uncovering the eyes. Walsh (1957) is of the opinion that formed visual hallucinations are due to involvement of the temporal lobe, and cites both experimental and clinical evidence to substantiate this point. A differing view is held by Weinberger and Grant (1940), who believe that no such strict localization exists within the cerebral hemispheres, such hallucinations representing psychological phenomena involving the total integrative activity of the mind, the formed imagery depending on consititutional factors, not on cortical psychic organization. In his summary, Walsh prefers to accept the localization of such phenomena to the temporal lobe, founded on the available experimental and clinical evidence. Both patients whose cases have been described show marked complacency to their respective visual symptoms, and it is postulated that this euphoria may also be connected with the intracranial occlusive episodes of cranial arteritis.

Summary

Two cases of cranial arteritis, both manifesting formed visual hallucinations as a disturbing symptom, are described. The mode of presentation differed; in one case this symptom preceded the onset of unilateral loss of visual acuity and subsequently gave warning of impending visual loss in the other eye, whereas in the second case this symptom followed the occurrence of bilateral loss of vision. The subject of visual hallucinations and their possible relation to the known intracranial vascular pathology of this disorder are discussed.

I wish to thank Mr. A. Stanworth, Dr. A. W. D. Leishman, and Dr. T. W. May for permission to publish these cases.

Effect of an Oral Contraceptive Immediately Post Partum on Initiation of Lactation

TEIT KÆRN,* M.D.

Brit. med. J., 1967, 3, 644–645

Oestrogens are known to suppress lactation, and are often used for this purpose. The oral contraceptives currently available contain oestrogens and progestogens in varying doses. In some the progestin component itself has oestrogenic qualities (Paulsen, 1965), and treatment with this group might be expected to impair lactation to a marked extent. Rice-Wray (1964) reported that in about half of the lactating mothers she studied the milk yield was diminished by oral contraceptives. This seems to be a dose-dependent effect, for Pincus (1965, p. 262) noted that the percentage inhibited decreased from 77 to 15 as the norethynodrel dose was reduced from 20 to 2.5 mg./day. Satterthwaite (1964) thought that a 2.5-mg. dose of norethynodrel did not significantly affect lactation, but in her study there were no controls and the small number of patients makes generalization difficult.

Of oral contraceptive preparations currently available Norinyl-1 (norethisterone 1 mg. and mestranol 0.05 mg.) has the lowest total steroid content. Furthermore, norethisterone is antioestrogenic in some of its effects. In view of Rice-Wray's findings and Pincus's suggestion of a dose-dependent effect it seemed important to test the action of Norinyl-1.

The immediate post-partum period is the most convenient time to advise on contraception, and if the agent can be prescribed at this time follow-up problems are considerably reduced. This aspect is of prime importance in the developing countries, where the immediate post-partum period may be the only opportunity for contraceptive treatment, and where breast milk may be the infants' only source of protein.

Most studies of the effects of oral contraceptives on lactation have not been controlled, and since many factors influence lactation this reduces their value.

Methods

All mothers delivered in the obstetrics unit of St. Joseph's Hospital, Copenhagen, during the period July–September 1966 entered the trial, with the exception of (1) mothers who it was decided, before or immediately after delivery, should not attempt to breast-feed, and (2) mothers who gave birth to infants weighing less than 2,000 g.

A total of 451 women took part in the trial. Tablets were supplied by Syntex Pharmaceuticals Limited, England, in small containers marked only with a code number and containing 21 tablets. The code was not disclosed in Denmark until the trial had been completed, but it was known that some of the tablets were Norinyl-1 and others were inert placebo tablets. Each woman included in the trial received one tablet daily from the day after the birth of her child until discharge from hospital on the eighth day.

The relevant details of each case were recorded on a form which included the mother's previous history of breast-feeding, the code number of the tablets taken, and the baby's birth weight. A trained nurse accurately recorded on a decimal balance in the lying-in ward the weight of the babies on the second, fifth, and eighth days. The nursing staff were asked to assess the influence of the tablets on the onset of lactation. They recorded observations on the ease and adequacy of lactation, the state of the breast and nipples, and whether the patient was fully breast-feeding, complementary feeding, or completely artificially feeding.

---

* Chief Physician, Maternity Department, Saint Joseph's Hospital, Copenhagen.

Ten patients from each group were asked to continue their pills at home for a further two weeks and on completion to return to the hospital a questionary concerning the progress of lactation.

During the latter part of the trial observations were made with respect to the quantity of uterine haemorrhage, the type of lochia, after-pains, and the rate of involution of the uterus. These were not quantitated, however, and their assessment was purely clinical.

Results

Breast-feeding was discontinued in 33 infants. The reasons are given in Table I, from which it can be seen that the incidence of illness in infants of both groups is almost equal.

Of the 33 infants discharged from hospital on complementary feeds, 26 were from the remaining 212 women receiving the active Norinyl-1 tablets and seven were from the 218 women who were receiving the placebo tablets (Table II).

TABLE I.—*Infants Removed From the Trial and Sent Home on Artificial Feeding*

	233 Taking Norinyl-1		218 Taking Placebo	
	Primips 107	Multips 126	Primips 115	Multips 103
Illness in mother	0	1	0	1
Previous absence of lactation	0	2	0	0
„ breast operation ..	1	0	0	0
Inverted nipples	0	1	1	0
Illness in infant	8	5	6	4
Twins	3	0	0	0
	12	9	7	5

TABLE II.—*Incidence of Complementary Feeding by Parity and Tablet Received*

	Norinyl-1 (212)		Placebo (206)	
	Primips	Multips	Primips	Multips
Fully breast-feeding ..	83	103	103	96
Complementary feeding ..	12	14	5	2
	95	117	108	98

Of the 117 multiparous women who received Norinyl-1 tablets 14 needed to use complementary feeds, and of the 98 who received placebo tablets only two required complementary feeds. This difference was found to be significant at the 1% level ($\chi^2=7.6185$ on 1 degree of freedom). Of the 95 primiparae receiving active Norinyl-1 tablets 12 had to use a complement, while of the 108 who received the placebo only five had to give a complement. The difference is found to be significant at the 5% level, but not at the 1% level ($\chi^2=4.2020$ on 1 degree of freedom). The overall effect when the primiparae and multiparae are grouped together is that Norinyl-1 appears to diminish significantly the quantity of milk produced, as measured by the number of times complementary feeding was found necessary ($\chi^2=11.9114$ on 2 degrees of freedom). Lactation was not inhibited in these patients by Norinyl-1 or placebo tablets, and it was not necessary to resort to full artificial feeding.

The weights of the infants in the two groups have been compared. For this purpose birth weight has not been used, as this was estimated on a spring-balance in the labour room; the difference between the second-day and eighth-day weights has been taken as an estimate of weight change during the first week of life. If we exclude the infants receiving part or total artificial feeding and group together those of primiparous and multiparous mothers, then 186 infants from the Norinyl-1 group and 199 from the placebo group were breast-fed. In the Norinyl-1 group there was an average loss of weight during the first week of 6 g., while in the placebo-treated group there was an average gain of 15 g. The standard error of the difference of these two means is 12 g. Thus the infants who were wholly breast-fed showed no significant change in weight over the first week whether their mothers received Norinyl-1 or placebo tablets ($0.10>P>0.05$). From this trial it was not possible to assess whether a significant weight difference would appear at a later date.

Febrile breast engorgement was not significantly different in the two groups: Norinyl-1, 2 out of 233 cases; and placebo, 5 out of 218 cases. Feeding difficulties (psychological and mechanical) were encountered in approximately equal numbers in both groups, which amounted to 7%.

Discussion

This trial was concerned only with the effect of Norinyl-1 on the initiation of lactation and was confined to observations made in the first week post partum. In no case was the initiation of lactation suppressed by the drug.

A larger number of women in the Norinyl-1 group had to give their babies supplementary feeds than was observed in the placebo group, and this difference was statistically significant: there was a measurable diminution in the quantity of milk. The number of cases of febrile engorgement of the breasts in the Norinyl-1 group tended to be lower than that in the placebo group. Most of the women (88%) could feed their babies without any artificial complement after taking Norinyl-1 from the first day after birth. The woman who is anxious to breast-feed her baby would be best advised not to use Norinyl-1 until her baby is weaned, or at least until lactation is well established.

The follow-up of the 20 patients who continued treatment at home for three weeks was unsatisfactory, as only eight taking Norinyl-1 and eight taking placebo returned their questionaries. Four of the mothers on Norinyl-1 reported that they were still fully breast-feeding and four were having to give complementary feeds. The eight women who were on the placebo were still fully breast-feeding.

As previously mentioned, observations were made on the state of uterine involution in the latter half of the trial. The impressions of the observers were that there was no difference between the women on Norinyl-1 and those on the placebo.

Summary

A total of 451 women were given either Norinyl-1 (norethisterone 1 mg. and mestranol 0.05 mg.) or an inert placebo once daily from the day after birth under double-blind conditions.

In no case was lactation inhibited by the drug. Complementary feeds were given by 12% of the women taking the active tablet and by only 3.5% of those receiving placebo.

There was no significant difference in the change in weight of the infants in the two groups during the first week, though there was a tendency for the treated ones to gain less.

The incidence of febrile breast engorgement appeared to be slightly lower in the group receiving the active drug.

Idiopathic Gangrene in African Children

A. G. G. TURPIE,* M.B., M.R.C.P.GLASG.; C. D. FORBES,* M.B., M.R.C.P., M.R.C.P.ED., M.R.C.P.GLASG.

Brit. med. J., 1967, 3, 646–648

Gangrene of the extremities in Africans with apparently healthy arteries is a well-recognized but uncommon clinical syndrome affecting the indigenous population of East Africa (J. R. M. Miller, personal communication, 1966; A. A. Khan, personal communication, 1966). Both sexes and all age groups may be involved, and the condition is not confined to any particular tribal group or localized geographical area.

This communication gives an account of three African children with apparently spontaneous gangrene of the extremities.

According to current concepts it is possible that under physiological circumstances both the coagulation system and the fibrinolytic system may be constantly active to maintain an intact patent vascular tree, the coagulation system laying down a thin layer of fibrin on the vascular endothelium to seal any gaps which may occur, and the fibrinolytic system removing such fibrinous deposits after they have served their haemostatic function. In the coagulation system the inert plasma protein prothrombin is converted by thromboplastin to thrombin, which in turn brings about the conversion of the soluble protein fibrinogen to insoluble fibrin.

A similar basic structure is seen in the fibrinolytic system; plasminogen, an inactive plasma globulin, is converted by activators to plasmin, a proteolytic enzyme which under suitable circumstances digests fibrin, with release of soluble products. Plasminogen activators are present in many tissues, and the evidence suggests that plasminogen activator in the plasma is responsible for physiological fibrinolytic activity in the blood. A urinary activator (urokinase) probably represents, in part at least, excreted plasma activator.

In terms of the postulated dynamic equilibrium between clotting and lysis, thrombotic vascular occlusion, and hence tissue necrosis, might be expected to ensue from either hypercoagulability, with a failure of the fibrinolytic system to respond with increased activity, or from reduced fibrinolytic activity, in the presence of a normal coagulation mechanism (Fig. 1). In such circumstances reduced fibrinolytic activity might be due either to deficiency of the components of the fibrinolytic system or to the presence of inhibitors of fibrinolysis. Accordingly, in the present study particular attention was paid to the coagulation and fibrinolytic mechanisms of the affected children.

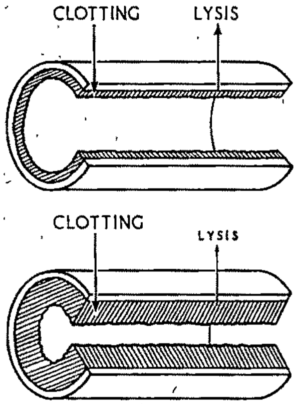

FIG. 1.—Above: the postulated dynamic equilibrium of the clotting and fibrinolytic systems. Below: how reduced fibrinolytic activity with normal clotting might be expected to lead to vascular occlusion.

Materials.—Streptokinase: A. B. Kabi, Stockholm. Urokinase: purified human urokinase was supplied by Abbott Laboratories, Chicago, Illinois. Thrombin: Parke Davis thrombin topical. Thromboplastin: Rabbit-brain thromboplastin. Dade Reagents, Miami, Florida. Casein: Casein of L. Light and Company, Colnbrook, Bucks.

Methods

Plasminogen Assay.—The method of Remmert and Cohen (1949) as modified by Alkjaersig *et al.* (1959) was used. The method is described by McNicol and Douglas (1964).

Fibrinogen Assay.—The plasma fibrinogen levels were measured by the method of Ratnoff and Menzie (1951) as modified by Alkjaersig (1960).

One-stage "Prothrombin" Time.—This was estimated by the method described by Douglas (1962).

Thrombin Clotting-time.—The method described by Fletcher *et al.* (1959) was used.

Thromboplastin Generation Test.—The method described by Biggs and Douglas (1953) was used.

Plasma Recalcification Time.—The method used was that of Biggs and McFarlane (1962).

Urokinase Sensitivity Test.—This was carried out as described by McNicol *et al.* (1963). In this test the lysis time of a plasma clot in the presence of a standard amount of urokinase is measured. Results are presented in arbitrary units, based on a double logarithm plot of lysis times against units of activity, and assigning one unit of activity to a lysis time of 10 minutes. In a patient with normal fibrinogen and plasminogen levels a prolonged lysis time in this urokinase sensitivity test reflects a high level of inhibitor of fibrinolysis.

Euglobulin Lysis Time.—This test was carried out by the method described by Nilsson and Olow (1962). In this test fibrinogen, plasminogen, and plasma plasminogen activators are precipitated from the plasma; antiplasmin is discarded with the supernatant and the precipitate is resuspended; after clotting with thrombin the lysis time is measured. As lysis times are inversely proportional to fibrinolytic activity, results are presented as suggested by Sherry *et al.* (1959) in arbitrary units of activity assigning to a lysis time of 300 minutes, one unit of activity. If plasminogen and fibrinogen levels are normal, variations in euglobulin lysis activity in a population can be regarded as a measure of variation in plasma plasminogen activator levels.

Case 1

A 7-year-old girl was admitted to hospital with an acute febrile illness of one day's duration. Until the onset of the illness the patient had been completely well. There was no history of drug ingestion. Clinical examination revealed a toxic febrile child with a widespread petechial rash. There was bluish discoloration of the tips of the fingers, which felt cold. The mucous membranes were pale but there was no icterus. Generalized non-tender lymphadenopathy and moderate enlargement of liver and spleen were present. The heart was normal and the blood pressure was 135/90 mm. Hg. The peripheral arterial pulses were readily palpable. Digital artery pulsation was present.

Gangrene of the fingers became evident soon after admission. Despite treatment with low-molecular-weight dextran (Rheomacrodex), corticosteroids, and penicillin, ischaemic changes appeared in the tips of the toes, and the feet later became gangrenous. Dorsalis pedis and posterior tibial pulses remained palpable in both feet. Amputation was recommended at this stage, but permission for operation was refused. Spontaneous sloughing of the gangrenous tissue of the finger-tips occurred (Fig. 2), and a clear line of demarcation developed in the feet.

The patient was discharged from hospital six weeks after the onset of the illness. She was readmitted two months later when the fore parts of the feet had sloughed; bilateral Syme's amputation was carried out. She was discharged well after a further four months in hospital.

The most striking laboratory feature of the acute phase of the illness was autohaemagglutination. This was so pronounced that standard cross-matching of the patient's blood was impossible. Cold agglutination titre was not estimated but marked autoagglutination was noted at room temperature (18.1° C.), and slight agglutinating activity was present at 37° C. The full clinical history and an investigation of this patient have been documented by Othieno-Okanga (1966). The patient's coagulation and fibrinolytic mechanisms were studied during her second admission to hospital some four months after the acute episode of the illness.

Case 2

A female child aged 2 years, with a month's history of a generalized weeping erythematous rash which had been treated unsuccessfully as scabies, was admitted to hospital with the acute onset of necrosis of the tips of her fingers and toes. There was no history of drug ingestion.

Clinical examination revealed an ill child with symmetrical peripheral gangrene of the tips of the fingers and toes. Peripheral pulses, including the digital artery pulsations, were normal. There was no lymphadenopathy and the liver and spleen were not enlarged. Neither auto-agglutination nor cold agglutination was demonstrated. The gangrenous lesions remained apparently uninfected and ultimately sloughed. The patient unexpectedly died after four weeks in hospital.

At necropsy, lobar pneumonia was the only gross lesion demonstrated. Histological examination showed the vascular tree, including small arteries supplying the gangrenous tissue, to be patent. There was, however, organizing thrombus in one vein draining the gangrenous area.

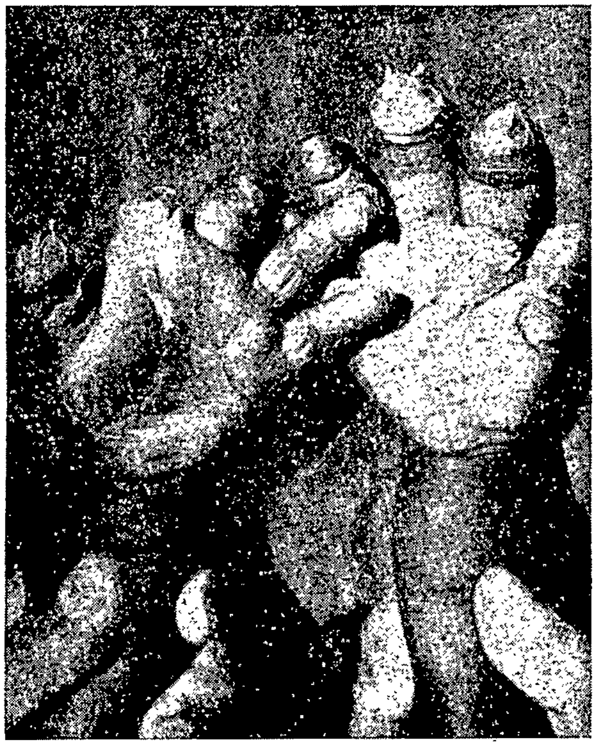

Fig. 2.—Case 1. Necrotic changes in the hands.

Studies of the fibrinolytic and coagulation mechanisms were carried out in the acute phase of the patient's disease.

Case 3

A male child aged 16 months had an illness of insidious onset of some weeks' duration. It was heralded by generalized itching, followed by the development of ulceration of the tips of his fingers. Before admission to hospital necrosis and sloughing of the tip of the little finger of the right hand developed acutely.

Apart from the gangrenous extremities clinical examination was normal. All peripheral pulses, including the digital pulses, were palpable and normal. The red blood cells showed rouleaux formation, but no agglutinins were found in the serum. Studies of the fibrinolytic system and clotting mechanisms were carried out in the acute phase of the illness.

In none of the three cases was there clinical or epidemiological evidence to suggest that they were suffering from ergot poisoning.

Controls

Plasma for control studies was obtained from age-, sex-, and tribe-matched patients from the paediatric and general medical wards who were suffering from a variety of miscellaneous illnesses not known to affect the haemostatic mechanism.

Results

In Fig. 3 recalcification times, thrombin clotting-times, and prothrombin times for the three patients are shown plotted against the mean and standard deviations of the values obtained from the control subjects. The plasma fibrinogen levels in the patients and the controls are shown in Fig. 4.

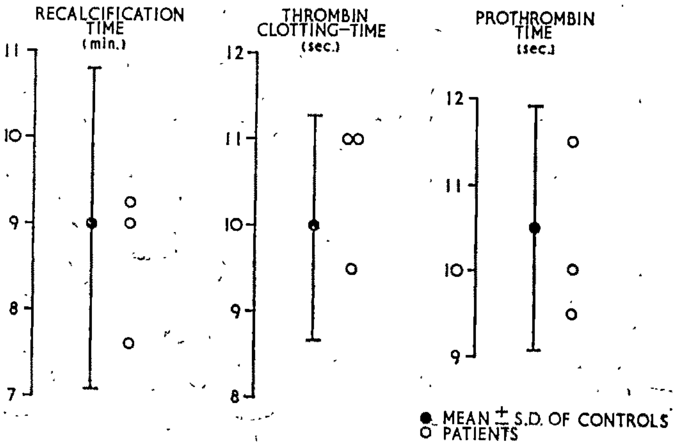

Fig. 3.—Coagulation studies performed in patients compared with the results in control subjects.

In all three patients the thromboplastin generation was normal; one (Case 1), who had purpura, had a platelet count of 72,000/cu.mm.—platelet counts in Cases 2 and 3 were normal. It therefore appears that, apart from the low platelet count in Case 1, the clotting mechanism in all three patients was normal.

Fig. 5 shows that the patients' plasminogen levels are within the range found in the controls. As plasma fibrinolytic activity is known to be low at birth and to increase over the first year or two of life (Samartzis and Cook, 1960), results for euglobulin lysis times in each patient are shown plotted separately, with controls age-matched for each patient (Fig. 6). The data in the controls confirm an increase in fibrinolytic activity with age; and in each case activity in the patient was much depressed compared with that found in the appropriate control population.

The results of the urokinase sensitivity tests from each patient are again shown with the appropriate age-matched controls, and in the controls increased lytic activity in response to urokinase can be seen (Fig. 7). All three patients show greatly reduced response to urokinase as compared with their controls.

Discussion

The results presented show that in the children studied there was a significant depression of spontaneous plasma fibrinolytic activity as compared with age- and sex-matched controls, and there was also a reduction in plasma fibrinolytic activity produced in response to a standard amount of plasminogen activator. In the euglobulin lysis technique, fibrinolytic inhibitors are discarded during preparation of the euglobulin clots, and as plasminogen and fibrinogen levels were normal the results suggest that the plasma from the patients had an abnormally low level of plasminogen activator. The reduced lytic activity in response to urokinase suggests that the patients' plasmas also contained an increased amount of fibrinolytic inhibitor.

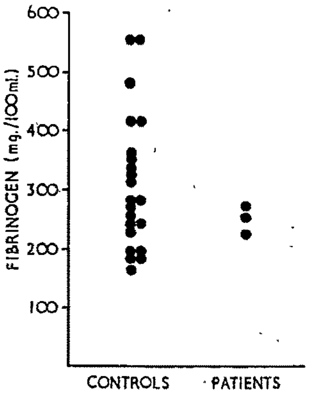

FIG. 4

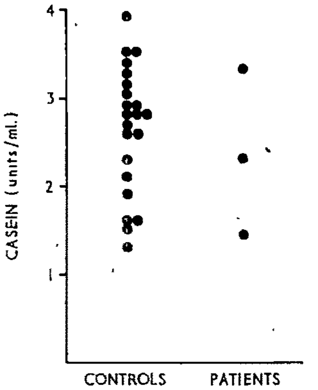

FIG. 5

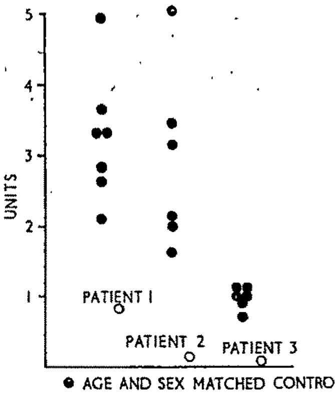

FIG. 6

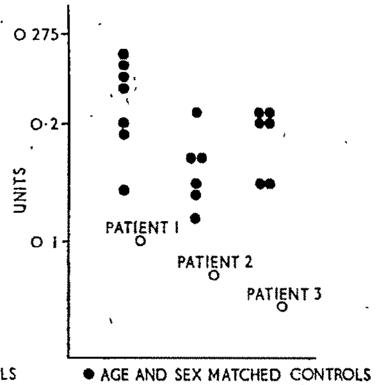

FIG. 7

FIG. 4.—Fibrinogen levels in patients and controls. FIG. 5.—Plasminogen levels in patients and controls. FIG. 6.—Euglobulin lysis times, presented as units of activity (see text), for each patient compared with age-matched controls. FIG. 7.—Urokinase sensitivity tests for each patient compared with the results for age-matched controls. Results are presented in units (see text).

Theoretically, inhibitors of fibrinolytic activity might be expected to act at two levels—inhibition of plasminogen activation and inhibition of formed plasmin. There are at least two antiplasmins in plasma (Norman and Hill, 1958), and platelets also show antiplasmin activity. There is inferential but not conclusive evidence that plasma also possesses anti-activator properties (Paraskevas *et al.*, 1962). The techniques used in the present study do not serve to differentiate between elevated levels of anti-activator and high antiplasmin content. No data are available as regards the basic cause or possible precipitating factors involved in this syndrome. There was no evidence of poisoning or of dysproteinaemia, nor does the condition appear to be genetically determined; an unidentified environmental factor seems the most probable explanation.

Though a causal relation between the abnormalities in fibrinolysis and the gangrene was not established, the association is of considerable theoretical and possibly also therapeutic interest. There are, so far as we can ascertain, only three reports in the literature of an increase in the levels of naturally occurring fibrinolytic inhibitor associated with severe widespread thrombotic disease (Nilsson *et al.*, 1961; Nilsson *et al.*, 1966; Brakman *et al.*, 1966). The finding in the present patients of reduced levels of fibrinolytic activity and increased levels of fibrinolytic inhibitor, in association with tissue necrosis presumably due to thrombotic vascular occlusion, provides support for the concept of a homoeostatic function for the fibrinolytic system in vivo. It would also seem possible that a trial of therapy with fibrinolytic enzymes given early in the evolution of the disease would be worth while.

Summary

Peripheral symmetrical gangrene of unknown origin is a well-recognized but uncommon syndrome affecting all ages and both sexes of the indigenous population of East Africa.

The clotting and fibrinolytic mechanism of three children who suffered from this "disease" were studied. Tests of blood coagulation showed no abnormality in the patients. Of the tests of the fibrinolytic mechanism, plasminogen and fibrinogen assays were normal in each case. The euglobulin lysis time, a measure of overall spontaneous fibrinolytic activity, was grossly prolonged in each case, and the urokinase sensitivity test, a measure of plasma inhibition of fibrinolysis, was markedly reduced.

The results show that in the children studied there was a significant depression of spontaneous plasma fibrinolytic activity due in part to increased levels of fibrinolytic inhibitors.

The significance of these findings is discussed in the light of the postulated dynamic equilibrium between coagulation and fibrinolysis in the maintenance of a patent vascular tree.

We are grateful to Dr. H. P. Ojiambo and Dr. A. A. Khan for permission to study patients under their care, and to Professor S. Alstead and Professor A. S. Douglas for their interest in the work.

Single-dose Treatment of Acute Urinary Tract Infection: a Controlled Trial

R. N. GRÜNEBERG,* M.B., B.S.; W. BRUMFITT,† M.D., PH.D., M.R.C.P., M.C.PATH.

Brit. med. J., 1967, 3, 649–651

Patients with acute urinary tract infection are usually seen and treated by their family doctor, and the majority either do not stay away from work or return to work as soon as the symptoms are relieved. Though a seven-day course of treatment with a number of antimicrobial agents will eradicate most infections, the relief of symptoms and return to normal activities results in some patients not completing the full course. This leads to a number of infections persisting in an asymptomatic form.

Sulphormethoxine (Fanasil) is a sulphonamide with a half-life in the body of about 150–200 hours (Haegi, 1966), and if therefore a seven-day course is required a single-dose treatment is feasible.

We have carried out a trial to compare this treatment with a seven-day course of ampicillin, which is established as an effective treatment of primary urinary tract infection.

Materials and Methods

Examination of Urine.—Midstream specimens of urine were collected by the clean-catch technique after cleansing with a swab moistened in sterile water. Quantitative bacterial and white cell counts were carried out. The sole criterion of infection was a count of 100,000 bacteria or more per ml. of urine. Organisms were identified by conventional methods, and the O antigen of *Escherichia coli* strains was identified by means of specific antisera.

Serum Antibodies.—Antibodies in the patient's serum against infecting organisms were estimated as previously described (Percival, Brumfitt, and de Louvois, 1964). A titre of 1:320 or more was taken to indicate renal involvement whether localizing symptoms were present or not.

Antibiotic Sensitivities.—These were carried out on para-aminobenzoic-acid (P.A.B.)-free sensitivity agar (Oxoid) with discs containing either 200 μg. of sulphormethoxine or 25 μg. of ampicillin. The plates were lightly inoculated with a wire loop from a single colony of the organism to be tested, the density of the inoculum and activity of the disc being controlled by inoculating the plate in a similar way with *Staphylococcus aureus* (Oxford strain N.C.T.C. 6571). Subsequently the minimal inhibitory concentration was estimated in tubes by the serial dilution method, using a final bacterial density of about 200 organisms per ml. For sulphonamide P.A.B.-free medium was used.

Patients

One hundred and four patients who visited their family doctor with symptoms of urinary tract infection were referred immediately to us for investigation and treatment. Each patient was seen by the same observer (R. N. G.), a full history was taken according to a standard questionary, and the patient was then examined clinically. A specimen of urine was collected and a blood specimen taken for measurement of the serum antibody level against the O antigen of the infecting organism.

If typical symptoms of urinary tract infection were present and no treatment had already been given the patient was admitted to the trial. Treatment was decided by the selection of a random number and the patient was given either a single dose of 2 g. of sulphormethoxine or 500 mg. of ampicillin eight-hourly for seven days.

Follow-up was carried out two and six weeks after the first visit. Patients were again asked about symptoms, a midstream specimen of urine was collected, and blood was taken for antibody determination.

Treatment was judged to have been successful if both follow-up specimens of urine were sterile, and to have failed where the organism originally isolated persisted.

Results

Treatment was given to 104 patients who had typical symptoms, but examination of the urine showed that only 50 of these had significant bacteriuria; therefore assessment of the relative chemotherapeutic value of sulphormethoxine and ampicillin was confined to the latter group of patients.

TABLE I.—*Comparison of Clinical and Laboratory Findings in the Two Groups*

	Sulphormethoxine	Ampicillin
Patients treated	25	25
Females	24	21
Average age	38·0	45·3
Previous history of urinary infection ..	18	17
Loin pain	5	5
Infections due to *E. coli*	20	17
Infections due to *Proteus mirabilis* ..	4	6
Infections with urine W.B.C. > 10/cu. mm.	22	23
Serum antibody titre ≥1/320	5	10
Serum antibody titre ≥1/640	4	6

Table II shows that cure rates were the same with sulphormethoxine and ampicillin, both substances being successful in 22 (88%) of the 25 patients in each group. The three patients who failed to respond to ampicillin all had very high serum antibody titres against the infecting organism, which suggested extensive renal tissue involvement. In two of the three ampicillin failures the organism responsible for the infection was sensitive to sulphormethoxine, as judged by in-vitro testing. These two patients were treated with sulphormethoxine and one was cured.

TABLE II.—*Results of Treatment*

Treatment	No. Treated	Cured (6-week Follow-up)
Ampicillin	25	22 (88%)
Sulphormethoxine	25	22 (88%)

The three patients who were not cured by sulphormethoxine were given a seven-day course of ampicillin and one was cured. The other two subsequently failed to respond to several courses of other antimicrobial substances.

* Research Registrar, Edgware General Hospital, Edgware, Middlesex.

† Pathologist, Edgware General Hospital; Senior Lecturer, St. Mary's Hospital Medical School, London W.2.

Requests for reprints to Dr. W. Brumfitt, Edgware General Hospital, Edgware, Middlesex.

The three patients who failed to respond to both sulphormethoxine and ampicillin were later investigated radiologically and all were found to have urinary tract abnormalities.

The side-effects were assessed on all patients treated, regardless of whether or not they were subsequently found to have bacteriological evidence of urinary tract infection.

The 104 patients received 109 courses of treatment (three sulphormethoxine failures were given ampicillin and two ampicillin failures were given sulphormethoxine). Sulphormethoxine was given to 53 patients and two developed side-effects, whereas nine of the 56 given ampicillin developed side-effects (Table III). The difference is statistically significant ($0.05>P>0.02$). Side-effects with sulphormethoxine were minimal: one patient felt nauseated for one hour after taking the tablets, and the other had a rash for a similar period. With ampicillin side-effects were more troublesome. One patient had diarrhoea and pruritus ani for four weeks, and five others had diarrhoea for two weeks or more.

TABLE III.—*Side-effects*

Treatment	No. of Courses Given	No. of Patients with Side-effects
Ampicillin	56	9 (16·1%)
Sulphormethoxine	53	2 (3·8%)

Rashes occurred in five patients and were maximal on the arms and trunk and non-pruritic. The rashes did not intensify when treatment was continued, and no urticarial rash characteristic of classical penicillin hypersensitivity was seen. Details of the actual side-effects are given in Table IV. They were equally distributed between patients who had true urinary infection and those who had typical symptoms without infected urine.

TABLE IV.—*Details of Side-effects Observed*

	Ampicillin*	Sulphormethoxine
Diarrhoea	6	—
Nausea	—	1
Rash	5	1
Pruritus	2	—
Other	2	—

* Four of the 9 patients with side-effects showed more than one feature.

Interestingly, three patients who had typical symptoms but no infection when treatment was started were found to be infected at follow-up. One of these patients was subsequently found to have a urinary tract abnormality, and the other two infections were due to organisms resistant to the antibacterial substance used.

Discussion

In a previous study carried out in general practice we found that a seven-day course of sulphadimidine cured 90% of patients with acute urinary tract infection (Mond, Percival, Williams, and Brumfitt, 1965), and in the present investigation 22 out of 25 patients were cured by the long-acting sulphonamide, sulphormethoxine, given in a single dose of 2 g. Ampicillin in conventional dosage cured the same number of patients with similar infections (Tables I and II).

The side-effects of ampicillin were more frequent than those due to sulphormethoxine, but it should be stressed that many of these would be accepted by patients confined to their home. However, effective treatment of patients with less severe clinical forms of urinary infection enabled them to resume normal activities, and under these circumstances side-effects were sometimes troublesome. For example, one patient who returned to work in a factory was unable to continue because of diarrhoea. Patients with side-effects also tend to discontinue the treatment.

The rashes which occurred after ampicillin have been ascribed to hypersensitivity (*British Medical Journal,* 1964), but the evidence for this is uncertain. The rashes were not urticarial and there were none of the other signs usually associated with penicillin hypersensitivity. Furthermore, in such patients skin tests can subsequently be shown to be negative (Stewart, personal communication).

With sulphormethoxine only a single dose was necessary, and therefore there was no danger of the patient forgetting or deliberately omitting to take the treatment. Side-effects were minimal, and many patients remarked favourably on the simplicity of treatment—particularly those who had previously been treated with other courses.

Previous studies have shown that where minimal inhibitory concentrations of sulphonamide are below 50 μg./ml. eradication of urinary infection can be expected, while minimal inhibitory concentrations in excess of 200 μg./ml. usually mean that the infection will prove to be resistant to sulphonamides. We found that 82% of organisms were sensitive to 50 μg. of sulphormethoxine per ml. or less, and these results agreed exactly with those found with sulphadimidine. It was also found that 87% of the organisms were sensitive to 5 μg. of ampicillin per ml. or less.

In the present study failure to respond to treatment was due to resistance of the infecting organism or to the presence of urinary tract abnormalities, and the three patients with sensitive organisms who failed to respond to both sulphormethoxine and ampicillin were all found to have such abnormalities when investigated radiologically.

There has recently been much discussion about the association of long-acting sulphonamides and the Stevens–Johnson syndrome (Carroll, Bryan, and Robinson, 1966 ; Harris, Wise, and Beveridge, 1966 ; Seneca, 1966). The syndrome may have a special association with sulphamethoxypyridazine, and it is said to be especially apt to occur in children (Harris *et al.,* 1966). Sulphonamides in general, together with a variety of other substances, have been associated with the Stevens–Johnson syndrome, but over the past five years we have observed several thousand patients treated with sulphadimidine and the long-acting compound sulphamethoxydiazine but have seen no example of the condition. Clearly a new compound must be used cautiously, and in view of the claim that the Stevens–Johnson syndrome is more likely to occur in children it would be best to avoid sulphormethoxine in paediatric practice until more experience has been gained in its use.

Recent but as yet unpublished experience on a very large scale during an outbreak of meningococcal meningitis, in which sulphormethoxine was used prophylactically in very high and repeated doses, has shown that the drug can occasionally produce skin reactions. These usually occurred in children, were mild, and followed a benign course. In some cases, however, they were generalized, more severe, and showed features of Lyell's syndrome (I. Lennox-Smith, personal communication).

The evidence that long-acting sulphonamides produce a more sustained hypersensitivity reaction than the short-acting compounds is in our view unimpressive, but of course no patient with a history of sulphonamide sensitivity must receive the compound.

Our findings suggest that for treatment of patients with urethrotrigonitis, such as we have described here, results will be as good as with the other antimicrobials at present available, while the side-effects and inconvenience to the patient are likely to be minimal.

In our view a long-acting compound of this variety is unsuitable for the treatment of patients with fever and evidence of acute pyelonephritis. Also, asymptomatic urinary infections in diabetic patients and pregnant women are more difficult to eradicate than the acute infections seen in general practice (Williams, Brumfitt, Leigh, and Percival, 1965), and the possible place of sulphormethoxine in these conditions remains to be defined.

Summary

Sulphormethoxine is a sulphonamide with a prolonged action, which makes possible the treatment of some varieties of acute urinary tract infection with a single dose of 2 g. In a controlled trial on ambulant patients it was as effective as a seven-day course of ampicillin given in a dose of 500 mg. eight-hourly. The cure rate was 88% with both substances. Side-effects occurred in 3.8% of patients treated with sulphormethoxine and in 16.1% of those who received ampicillin.

Sulphormethoxine is not recommended for acute pyelonephritis.

Dr. Grüneberg was in receipt of a grant from the North-west Metropolitan Regional Board. Dr. I. Lennox-Smith, of Roche Products Ltd., kindly arranged for a supply of sulphormethoxine.

Controlled Trial of Methandienone in Treatment of Diabetic Retinopathy

P. R. HUNTER,[*] M.A., M.B., M.R.C.P.; SUSAN G. COTTON,[†] M.B., M.R.C.P.; J. H. KELSEY,[‡] M.B., F.R.C.S.
ARNOLD BLOOM,[§] M.D., F.R.C.P.

Brit. med. J., 1967, **3**, 651–653

Retinopathy is a common concomitant of diabetes and is related more to the duration of the diabetic state than to any other factor. Present methods of controlling the diabetic state are unable to prevent the onset or progress of retinopathy. Several studies have claimed that diabetic retinopathy is improved by the administration of anabolic steroids (Dardenne, 1961; Houtsmuller, 1961; Fabrykant *et al.*, 1964). Unfortunately the natural history of diabetic retinopathy is a variable one, and assessment of the value of therapy is correspondingly difficult. Leopold (1964) stated: "Further well controlled studies on the influence of anabolic steroids in diabetic retinopathy are mandatory."

In the present study methandienone (Dianabol) was chosen as an anabolic steroid which was effective when given by mouth, and retinal photography was used for the quantitative assessment of retinopathic changes. Forty-nine diabetic patients were observed, the double-blind method of comparing treated patients with controls being used.

Design of the Trial

Selection of Patients.—Diabetics with retinopathy of all grades of severity (except severe retinitis proliferans) were admitted to the trial provided they had clear media. The trial started in May 1965 and ended in March 1967. Patients below 20 or over 70 years of age and those with any major illness were excluded, as were those who were unlikely to co-operate. The patients came from the diabetic clinics of a teaching and a district hospital.

Treatment and Supervision.—The patients were divided by random numbers into a group receiving oral methandienone 5 mg. twice daily and a group receiving a placebo tablet of the same size and colour, also twice a day. Patients were observed for an average of one year (span 6 to 22 months). They were seen monthly, and the following factors were among those recorded: blood pressure, blood sugar (glucose oxidase method), serum cholesterol (Carr and Drekter, 1956), serum aspartate aminotransferase (Reitmann–Fränkel units). Side-effects and regularity of tablet-taking were also noted.

Visual Acuity and Retinal Photography.—Visual acuity was measured before treatment, Snellen type being used. Thereafter it was assessed six-monthly. Refractive errors were corrected when present. Retinal photographs were taken on Kodachrome 2 film with a Kowa or Zeiss retinal camera. Initially multiple fields were recorded, but eventually a series of standardized fields (nasal, inferior temporal, and superior temporal) were taken of each eye. The objective was to produce three comparable fields per eye at six-monthly intervals.

Assessment of Retinal Photographs

Two assessors were present for all assessments. Standard retinal photographs as defined by Oakley *et al.* (1967) were used for grading the retinopathy. This system comprises the following features.

(1) The patient's photographic fields are graded by direct comparison with a set of standard fields. The grading for a whole fundus represents the average for the individual fields comprising the fundus.

(2) Five diabetic retinal abnormalities are featured:

(*a*) *Microaneurysms and Haemorrhages.*—These include all "dots" and "blots" on the retina, but exclude vitreous haemorrhages. The grading is according to the number of lesions present in the field regardless of their size.

(*b*) *Exudates.*—Hard exudates only, soft ones being ignored. As confluent exudates are common *the area of retina involved*, rather than the number of lesions, is used for grading.

(*c*) *New Vessels.*—All abnormal vascular channels, excepting those forming in relation to previously established fibrous retinitis proliferans. Grading according to the area of field involved.

(*d*) *Venous Irregularities.*—All venous irregularities, including dilatation, segmental irregularities, and "sausaging." Grading according to length of veins involved.

(*e*) *Retinitis Proliferans.*—Any fibrotic lesion in front of the retina, regardless of its vascular associations, and including any detectable diffuse veiling over the retinal surface. Grading according to the area of field involved.

---

[†] Medical Registrar, Whittington Hospital, London N.19.

[‡] Consultant Ophthalmological Surgeon, University College Hospital, London W.C.1.

[§] Consultant Physician, Whittington Hospital, London N.19.

Soft exudates may be a specific part of diabetic retinopathy but are not included in this classification.

(3) For each retinopathic feature four standard fields, A, B, C, and D, enable five grades of severity to be determined.

No lesion	Grade 0
Lesion present but less than standard A	Grade 1
Equal to or worse than A but better than B	Grade 2
Equal to or worse than B but better than C	Grade 3
Equal to or worse than C but better than D	Grade 4
Equal to or worse than D	Grade 5

(4) *Scoring System.*—In order to arrive at a quantitative assessment each field was given the appropriate number for each retinopathic feature. The total of the grade numbers was divided by the number of fields to produce an average value for each feature per eye. A change for better or worse was defined as a change in one grade number in two out of three fields, or of two grade numbers in one out of three fields. In the majority of patients finally analysed two complete sets of three fields were available for each eye. Where fields showed slightly different areas non-matching parts were excluded.

Results

Sixty-two patients were admitted to the trial. Two died and 11 were withdrawn because of side-effects, unreliability, or moving out of the area. Of the 49 remaining patients, five could not be included because their photographs were not good enough. In a further 10 patients only one eye was studied for the same reason. The total material available for study therefore constitutes 78 eyes—45 in the placebo group and 33 in the treated group. The two groups were basically similiar in respect of the initial severity of their retinopathy, the methods of treatment of their diabetes, the degree of hyperglycaemia, and the length of observation of their retinopathy.

Haemorrhages.—Patients taking methandienone showed a higher percentage of deterioration than occurred in the control group. Six patients in the treated group deteriorated as against four in the control group (Table I). In those who deteriorated the haemorrhages were more severe in the treated than in the untreated group, since in the treated group (10 eyes) the average grade number rose by 1.7 as against a rise of 1.06 in the control group (5 eyes). It was also noted that the haemorrhages tended to be large and multiple in the treated group. Improvement in haemorrhages occurred in only one patient in the treated group whereas it occurred in four patients in the control group. In 37.7% of controls and 48.8% of treated patients one field in six was not usable, deficiencies which cancel each other out as the error produced was in the same direction.

TABLE I.—*Haemorrhages in Treated and Control Groups*

	Placebo			Methandienone		
	Both Eyes	Only One Eye Available	Percentage of Total Eyes	Both Eyes	Only One Eye Available	Percentage of Total Eyes
Improved	1	3	11·1	0	1	3·0
No change	12	11	77·8	8	6	66·7
Deteriorated	1	3	11·1	4	2	30·3
Total eyes	45			33		

Exudates.—Treatment with methandienone was not associated with any overall beneficial effects on hard exudates. In a total of 15 eyes in the treated group five improved and five deteriorated, compared with the placebo group, in which in a total of 28 eyes four improved and five deteriorated. Though a higher percentage showed an improvement in the treated group, there was also a higher percentage of those who deteriorated. Two patients on methandienone showed significant improvement for exudates in one eye while deteriorating significantly in the other.

Other Lesions.—New vessels were seen in six patients, all of whom were receiving placebo tablets. In two of the six the new vessel lesion became more severe during the trial. Retinitis proliferans developed in two patients, both of whom were receiving placebo tablets. In two other patients also receiving placebos mild retinitis proliferans present at the beginning became more severe during the trial. Venous changes were not analysed because discrepancies between observers' findings made results too inconsistent to be of value.

Visual Acuity.—This was regarded as changing significantly if vision altered by two lines on a Snellen chart. Placebo and treated patients did not appear to differ significantly as regards alterations in their visual acuity. Of 25 treated patients, nine improved and two deteriorated. Of 31 untreated patients nine improved but seven deteriorated. The patient's sex did not have any consistent effect on retinal response to methandienone.

Side-effects.—Frequent questioning established that the patients took their tablets regularly. Of 30 patients on methandienone, three developed oedema, three heart failure, two a persistent rise in diastolic blood pressure, two unsteadiness on the feet and headaches, one acne and voice change, and one increased libido. In the control group (32 patients) one patient developed oedema and another heart failure, while two had a sustained rise of diastolic blood pressure. In both treated and placebo groups one patient died of a coronary thrombosis. It would seem that fluid retention and subjective symptoms occurred more frequently in patients on methandienone. However, it does not seem to have caused hypertension. Serum cholesterol rose on average by 108 mg./100 ml. in the treated group, as against 43 mg./100 ml. in the untreated group. In both groups a small rise in serum transaminases occurred.

Discussion

Visual acuity is the most important of all measurements from the patient's point of view, but is an inadequate guide to retinal changes. A small haemorrhage in the region of the macula may cause a considerable loss of vision while a larger haemorrhage more peripherally may scarcely be noticed. Also, visual acuity is diminished by changes outside the retina in the lens or vitreous.

Assessment of changes in the retina can be attempted by direct ophthalmoscopy, but this clearly does not allow detailed comparison. The use of a binocular ophthalmoscope enables the fundus to be drawn while actually under observation, but this method is very time-consuming and is open to observer bias (Davis, 1965 ; Lee *et al.*, 1966).

The retinal camera offers the best objective method of assessing changes in the retina, but it has several disadvantages. Changes in the lens or the vitreous may make photography impossible, and in some patients, particularly negroes, the pupils dilate too slowly and incompletely. It is impracticable to attempt a complete fundus map and difficult to be sure of getting comparable fields when smaller areas are examined. In this study three fields for each eye were chosen (nasal, inferior temporal, and superior temporal), and these proved adequate in practice. Nevertheless, some cases had to be discarded because the fields in series were not regarded as sufficiently comparable.

When a series of comparable retinal photographs has been obtained, the next problem to be solved is that of standards of comparison. The natural history of retinopathy is a variable one. Each component of diabetic retinal pathology may progress, regress, or remain unaltered. Haemorrhages, exudates, new vessel formation, venous dilatation, all may come and go. In this study, and in studies by other observers (Table II), about one-third of patients in the control group showed changes for better or worse while under observation. Hence there is an absolute need for standards of assessment, and in this respect the standard retinal photographs have proved of practical worth. Five retinopathic abnormalities have been photographed in four standard degrees of severity, and the photographs under study were graded according to these standards. In this way not only was it possible to define deterioration or improvement, it was also possible to devise a simple quantitative assessment of the extent of the changes. With the exception of venous changes, observer errors in assigning grades was slight and results were found to be reproducible.

* Personal communication.

Methandienone was chosen as an agent known to be an effective anabolic steroid given by mouth, and the dosage of 5 mg. twice daily was sufficient to induce an average rise of serum cholesterol of 108 mg./100 ml. as compared with a rise of 43 mg./ 100 ml. in the control group. In an ailment such as diabetes mellitus, which is known to be associated with vascular disease, this cholesterol elevation must be regarded as an unwelcome effect, especially in the long term.

The effects of methandienone on diabetic retinopathy were compared with those of placebo tablets by means of the familiar double-blind technique in which neither patient nor observer was aware of the nature of the tablets used. Assessment of the changes at the end of 18 months seemed to show an increase of haemorrhages in patients taking methandienone, and though this was not statistically significant ($P>0.12$), it made it highly unlikely that even over longer periods any benefits would accrue.

Summary

Changes in retinopathy were assessed in two groups of diabetics, one receiving 10 mg. of methandienone daily and the other a placebo. No beneficial effect was observed in the treated group.

Assessment of changes in retinopathy was made by serial retinal photographs. These were compared with sets of standard photographs. This method of assessment proved effective and reproducible and could be used for future trials.

We acknowledge with gratitude the receipt of a grant from the North-West Metropolitan Regional Hospital Board. We are indebted to Dr. Terry Binns, CIBA Laboratories, Horsham, for his help in designing the trial and providing methandienone (Dianabol) tablets and to Mr. Peter Smith, of the M.R.C. Department of Statistics, for assistance in assessing the results. Finally we are grateful to Professor Sir Max Rosenheim for allowing us to include patients attending University College Hospital.

Preliminary Communications

Fibrinolytic Activity in the Clinical Crisis of Sickle-cell Anaemia

Brit. med. J., 1967, 3, 653–654

The natural history of subjects with sickle-cell anaemia is punctuated by recurrent clinical crises. There is rarely any evidence of acute haemolysis in the vast majority of episodes of crisis (Diggs, 1956), and emphasis has been placed on the finding of a variety of thromboembolic manifestations affecting almost every body organ. It is inferred that there is a marked tendency towards spontaneous vascular occlusion in sickle-cell anaemia though the mechanism remains unknown. A generally accepted conclusion is that thrombotic crises arise as a consequence of intravascular agglutination of sickled cells leading to local thrombosis and tissue ischaemia (Allison, 1956). Walters (1958) has suggested, however, that infarction might be precipitated by factors likely to influence the coagulability of the plasma, with subsequent precipitation of a fibrin reticulum within vessels. Abnormalities in coagulation factors have been reported in subjects with sickle-cell anaemia (McKellar and Dacie, 1958; Henstell *et al.*, 1965), but their relation to clinical crisis has not been investigated.

The present study is an attempt to assess whether the fibrinolytic mechanism is impaired in sickle-cell anaemia, both during periods of apparent well-being and during episodes of clinical crisis.

PATIENTS AND METHODS

Children attending the sickle-cell anaemia clinic or admitted to the paediatric wards at Mulago Hospital, Kampala, were studied. All blood samples were obtained between the hours of 11 a.m. and 2 p.m., and a clean venepuncture was carried out with minimum stasis. Dilute blood clot lysis was determined with the technique of Fearnley *et al.* (1957) as modified by Lackner and Goosen (1959). The disintegration of the clot was taken as the end-point in this study, and clots were followed for a maximum of 24 hours. The following groups of patients were studied:

Group A (37).—Hospital inpatients with haemoglobin phenotype AA and with a wide variety of disorders. The duration of their stay in hospital preceding examination ranged from 4 to 42 (mean 9) days.

Group B (77).—Subjects with sickle-cell anaemia attending as outpatients and apparently well.

Group C (7).—Subjects with sickle-cell anaemia attending with mild symptoms attributable to the disease, but not severe enough to necessitate their admission to hospital.

Group D (13).—Subjects with sickle-cell anaemia with symptoms attributable to the disease and severe enough to require their admission to hospital. These children were usually bled within 48 hours of admission.

RESULTS

The distribution of the lysis times obtained in the four groups is shown in the Table. In testing for the significance of differences between any two groups, both the actual lysis time in hours and the logarithmic equivalent were used; differences between groups were equally significant whichever value was employed. The Mann–Whitney U test was used for assessing the significance of differences between the groups (Siegel, 1956).

Distribution of Lysis Time in Hours

Hours	A	B	C	D
1	3	2	1	0
2	6	15	0	1
3	3	19	3	2
4	5	13	3	1
5	2	6	0	0
6	2	7	0	0
7	3	1	0	0
8	2	3	0	0
9	1	3	0	0
10	1	2	0	0
11	2	0	0	1
12	0	0	0	0
13	0	1	0	1
14	1	0	0	0
15	0	1	0	0
16	0	0	0	0
17	2	0	0	0
18	1	0	0	0
19–23	0	0	0	0
24+	3	4	0	7
	37	77	7	13

The most striking finding is that the lysis time in group D—that is, sickle-cell anaemia subjects in clinical crisis admitted to the ward—is far greater than in group A (P=0.008), group B (P=0.008), or group C (P=0.006). There is a suggestion that lysis time in the apparently well sicklers is longer than in those with mild symptoms (P=0.02). Lysis time in the children with haemoglobin phenotype AA is slightly longer than in "well" sicklers (P=0.05) or in sicklers with mild symptoms (P=0.04), but it is very likely that this reflects the effect on fibrinolytic activity of the various illnesses for which these children were admitted to hospital and the medication they were receiving—for example, corticosteroids.

DISCUSSION

Fibrinolytic activity is significantly lower in patients with sickle-cell anaemia in whom symptoms attributable to this disorder were severe enough to necessitate their admission to hospital. If the severe symptoms associated with clinical crisis are due to intravascular thrombosis, it is possible that the fibrinolytic mechanism may be involved in either the development or the maintenance of such vascular occlusion. There is presumed to be a dynamic equilibrium between the deposition of fibrin in vessels and its removal by lysis (Astrup, 1956; Fearnley, 1961); and the marked diminution in fibrinolytic activity during episodes of sickle-cell crisis might either reflect some factor inhibiting normal enzyme activity or may represent the body's response to intravascular thrombosis and tissue damage.

High levels of fibrinogen have been reported in older subjects with sickle-cell anaemia in America, though the finding was thought to be nonspecific. There appeared to be no difference in fibrinogen levels when patients were studied in or out of crisis (Fenichel *et al.*, 1950). This report of raised fibrinogen levels is commented upon because Blix (1961) asserted that clots made of plasma containing a high concentration of fibrinogen are more resistant to lysis than those formed from a lower fibrinogen concentration. However, Bennett *et al.* (1967) believe that the situation is far more complex than this and that changes in plasminogen activator, as assessed by euglobulin clot lysis, do not simply reflect changes in fibrinogen levels.

While it is possible that the subjects in sickle-cell crisis form a special group in whom there is a persistently reduced fibrinolytic activity, we think that this is very unlikely. It is more probable that activity is lowered during or before a severe clinical crisis. Four of the 13 patients studied in clinical crisis were studied again several months later, when they were apparently well. Of three subjects with long lysis times (24 hours) one remained prolonged and two had fallen to 3.9 and 3.3 hours respectively.

Several of the 13 children admitted in clinical crisis had haemoglobin levels below the level of those attending the clinic and not admitted to hospital. It has, however, previously been shown that the degree of anaemia per se does not affect fibrinolytic activity (Shaper *et al.*, 1967).

SUMMARY

Fibrinolytic activity has been shown to be significantly reduced in children with sickle-cell anaemia in clinical crisis as compared with sickle-cell anaemia subjects with no symptoms or with mild symptoms. Further studies are indicated to ascertain whether a disturbance of the fibrinolytic mechanism has a causal relationship to the signs and symptoms of the clinical crisis in sickle-cell anaemia.

We are grateful to Dr. M. C. Pike (Medical Research Council Statistical Research Unit) for his advice and assistance. This work is supported by grants from the Medical Research Council to A. M. and A. G. S. and by the World Health Organization.

Medical Memoranda

Embolism from Mural Thrombus in the Thoracic Aorta

Brit. med. J., 1967, **3**, 655–656

Mural thrombus in the internal carotid artery is a source of emboli to the retinal and cerebral arteries, causing transient or permanent blindness and hemiplegia (Gunning *et al.*, 1946b); thrombi in subclavian arteries damaged by cervical ribs form emboli which lodge in the digital arteries, inducing ischaemia of the fingers and thickened intima (Gunning *et al.*, 1964a). Emboli from mural thrombi in the popliteal artery have been implicated in gangrene of the great toe (Ross, 1936). Mural thrombi on plaques of nodular arteriosclerosis are common in the abdominal aorta, but the frequency with which they form emboli to the abdominal or leg arteries is unknown, the paucity of published cases suggesting the event is either uncommon or unrecognized.

Gross examples of a phenomenon are important because they are easily recognized and may be the extreme variants of events which are commonly unspectacular or undetectable. It is with this possibility in mind that a case in which mural thrombus in the thoracic aorta formed emboli to the abdominal and leg arteries is reported.

CASE REPORT

An unmarried woman (U.O.H. 363216) aged 67 had for many years noticed slight breathlessness and constricting pain in the centre of the chest when walking. She was admitted to a cottage hospital complaining of pain in the right loin, vomiting, and weakness for nine days. Her temperature was 99.6° F. (37.6° C.) and blood-pressure 190/90 mm. Hg. No abnormalities were found in the abdomen or chest. The urine contained moderate quantities of protein, but the centrifuged deposit showed neither red nor white cells. The blood urea was 53 mg./100 ml. Her pain continued for five days and several examinations failed to establish its cause.

She was transferred to the Radcliffe Infirmary, where examination showed a sinus rhythm of 96/minute. The only pulses in the legs were the femorals; her blood-pressure was 125/80 mm. Hg. Crepitations were present in both lungs, but there were no cardiac murmurs and no abdominal abnormalities. The urine had a specific gravity of 1018, it contained between 300 and 1,000 mg. of protein per litre, and the centrifuged deposit had 8 white cells and several hyaline and granular casts per high-power field. The blood urea was 48 mg./100 ml.; plasma sodium 130, potassium 4.2, chloride 90, and bicarbonate 20 mEq/l. The plasma amylase was 7 units. The haemoglobin was 99%; white cells 20,000/cu. mm.—a neutrophil leucocytosis; the sedimentation rate was 97 mm./hour.

The next day her loin pain increased and she complained of pain in the legs. Examination revealed tenderness in the right hypochrondrium. The following day her legs were cold and white, and bowel sounds were absent. On the third day she sweated profusely, the pulse was 120/minute and the systolic blood-pressure 50 mm. Hg, despite metaraminol and hydrocortisone. Faeculent material was aspirated from the stomach. She died on the seventeenth day of her illness.

Necropsy three days after death showed fresh infarcts of the same age in the spleen, intestines, and kidneys, the right kidney being completely infarcted. The corresponding arteries contained fresh thrombus, the right renal artery being occluded by thrombus which projected into the aortic lumen. The femoral arteries below the inguinal ligament did not contain thrombus; the leg arteries were not examined. A mural thrombus 3 cm. long occluded the first two intercostal arteries on the right side. The larger upper end was 1 cm. wide and 0.5 cm. deep; its surface was ragged and necrotic. The rest of the aorta showed moderate nodular arteriosclerosis, particularly below the renal arteries, where atheromatous ulcers were filled with thrombus. The coronary arteries showed moderately thickened intima, but they were patent. The heart valves were normal, neither the left atrium nor ventricle contained thrombus, and the foramen ovale was closed. The pulmonary veins were normal, the lungs were congested, and there were small pleural effusions.

The aortic mural thrombus was cut in half longitudinally and embedded in two blocks, from which sections were taken at 200-μ intervals. The ragged surface from the upper end was fresh fibrin thrombus surrounding granular platelet areas; its superficial irregularities were filled by a loose fibrin reticulum, leucocytes, and macrophages, which suggested either lysis of thrombus or thrombus lost as emboli. The centre of this fresh thrombus was necrotic. The underlying thrombus was hyaline fibrin on an intimal plaque 3 mm. thick. The large thrombus occluding the right renal artery was identical with the platelet fibrin thrombus from the thoracic aorta; in the remainder of this and the other occluded arteries there were small platelet fibrin thrombi and clotted blood. The infarcts in the spleen, kidneys, and intestines were the same age. There was no evidence of an arteritis.

DISCUSSION

The diagnosis of embolism requires a source for the embolus, distal arteries occluded by this material, and absence of multiple arterial thromboses or arteritis, all of which were found after death but not detected during life in this patient.

Mural thrombus in the internal carotid artery is suggested by reduced pulsation and bruits; it is confirmed by arteriograms, which in arteries of this calibre show irregularities of the arterial wall. In contrast, mural thrombus in the aorta is undetected, either clinically or radiologically, unless it is massive, because the remaining lumen is still large.

Transient occlusion of retinal and cerebral arteries by emboli is usually associated with striking symptoms and signs (Russell, 1963; Gunning *et al.*, 1964b); however, Skovborg and Lauritzen (1965) observed three symptomless retinal emboli in a diabetic patient. In a detailed clinicopathological study of aorto-iliac thrombosis Gunning *et al.* (in preparation) found extensive mural thrombus in these arteries, and on histological grounds suggested that emboli of mural thrombus and atheromatous material were to be expected. The case histories, however, did not reveal progress of ischaemic symptoms corresponding to the progressive thrombosis observed anatomically, nor did they suggest episodes of embolism. They concluded that the legs, unlike the retina, brain, and fingers, were not sensitive indices of arterial occlusion unless the blockages were substantial and lasting. Furthermore, Gunning *et al.*'s study of internal carotid endarterectomy specimens showed fresh mural thrombus if symptoms of retinal and cerebral ischaemia occurred in the seven weeks before endarterectomy, but fresh thrombus was not found in cases with a greater interval between symptoms and surgery. By analogy, fresh thrombus on aortic plaques is a potential source of emboli to the abdominal organs and legs; but to demonstrate such a relationship between mural thrombus and embolism in the lower limb requires extensive histological examination.

Deposits of mural thrombus on the intima of coronary arteries (Duguid, 1946) and aorta (Crawford and Levene, 1952) are organized to plaques identical with nodular arteriosclerosis, and homologous pulmonary thrombo-emboli in animals undergo similar changes (McLetchie, 1952). It is probable that emboli of mural thrombus impacted at arterial bifurcations or occluding small arteries are also incorporated into the arterial wall.

In this patient emboli from mural thrombus in the thoracic aorta occluded many distal arteries and caused death. It is likely that the mural thrombi commonly found in the abdominal aorta also form emboli to the legs, which are undetected clinically. The organization of these emboli would contribute to the intimal thickening universally found in the leg arteries of the elderly.

It is a pleasure to thank Dr. A. M. Cooke for permission to publish this case and Professor Sir George Pickering for his helpful criticism.

Chronic Milk-alkali Syndrome after Prolonged Excessive Intake of Antacid Tablets

Brit. med. J., 1967, 3, 656–657

Rifkind *et al.* (1960) reported the case of a woman who developed the clinical features of chronic milk-alkali syndrome following prolonged excessive consumption of Rennies tablets. We here report a second case, differing in the absence of generalized osteosclerosis.

CASE REPORT

A 40-year-old woman admitted to hospital for investigation on 13 May 1963 complained of excessive thirst for the previous eight years, and because of this her urine had been tested for sugar on several occasions, with negative results. She said that she had sustained rib fractures in 1960 and 1961, once when turning a mattress and once on sneezing. We were unable to obtain the *x*-ray films taken on these occasions. In July 1962 she first noted spontaneous twitching of the legs and itching of the skin of the trunk and arms. From March 1963 her ankles and feet felt stiff. She then became increasingly tired and found it necessary to give up her secretarial work. Two weeks before admission she had a solitary episode of dysuria, urethral pain, and frequency of micturition lasting for two days. Her appetite remained normal, there was no nausea or vomiting, and her weight was steady.

Further questioning revealed that she had consumed about 24 Rennies tablets daily since 1952. She first took this proprietary antacid to relieve heartburn in her second pregnancy. Heartburn did not recur after the baby was born, but she had acquired a taste for the tablets and continued to take them regularly. Each Rennies tablet contains mag. carb. pond. 78 mg., mag. hydrox. 2.9 mg., mag. oxid. lev. 3.4 mg., calc. carb. 671.6 mg., kaolin. lev. 3.4 mg., calc. phosph. 1.1 mg., and ol. menth. pip. 2.6 mg. The patient was therefore taking some 16 gm. of calcium carbonate daily, in addition to her normal dietary intake. She had also been given tablets containing calcium in 1961, after fracturing a rib, but had taken these for only about two weeks. There was no history of vitamin-D medication. Her average consumption of milk was less than 1 pint (570 ml.) daily.

On examination she did not appear acutely ill. Slight generalized brown pigmentation of the skin and numerous scratch marks on her back were present. There were calcium deposits on the nasal and lateral sides of both corneae, but no subcutaneous soft-tissue swellings or other abnormal physical findings. Her blood-pressure was 125/90 mm. Hg.

Investigations.—Haemoglobin 10.6 g./100 ml.; M.C.V. 92 cubic microns; M.C.H.C. 30.5%; W.B.C. 6,500/c.mm.; E.S.R. (Westergren) 68 mm./hr.; blood urea 261 mg./100 ml.; plasma sodium 136 mEq/l.; potassium 5.8 mEq/l.; chloride 95 mEq/l.; bicarbonate 21 mEq/l.; serum calcium 11.4 mg./100 ml.; phosphate 5.7 mg./100 ml.; alkaline phosphatase 7.9 King-Armstrong units; serum albumin 3.3 g.; serum globulin 3.5 g. A 24-hour urine sample (on 23 May) contained 0.34 g. protein, 94 mg. calcium, and 410 mg. phosphate. Urinary cell excretion (measured over four hours): W.B.C. 8,600,000/hr., R.B.C. 1,000,000/hr. Two mid-stream specimens of urine were cultured; one grew micrococci and the other *Escherichia coli* and *Streptococcus faecalis*. Mantoux test was negative, with 1/1,000 old tuberculin. Chest *x*-ray picture was normal and no evidence of generalized bone disease was seen on radiographs of the lumbar and thoracic spine, hands, or teeth, the lamina dura being intact. Plain *x*-ray films of the abdomen and renal tomograms showed small kidneys (each was 9.5 cm. in length) with diffuse parenchymal calcification. An attempt at renal biopsy was unsuccessful.

In hospital she accepted the advice to stop taking Rennies tablets and was given a low-protein diet with high oral fluid intake. By 24 May the blood urea had fallen to 150 mg./100 ml., and the serum calcium level was 9.6 mg./100 ml. and phosphate 6.8 mg./100 ml. She left hospital on 30 May, and in view of the probable urinary infection was given tetracycline, 250 mg. four times daily, to take at home.

She was readmitted on 6 June complaining of vomiting, thirst, and abdominal pain. She was clinically dehydrated, with blood-pressure 90/70 mm. Hg. The blood urea was 396 mg./100 ml. and plasma bicarbonate 9 mEq/l. She was given intravenous fluids with marked clinical improvement, the blood urea falling to 217 mg./100 ml. The serum calcium was 7.4 mg./100 ml., phosphate 8.7 mg./100 ml. She was discharged home for the second time on 16 June, taking sodium bicarbonate, 2 g. three times daily, to correct acidosis. She was still on this treatment at her most recent review in February 1966. She then looked and felt well apart from slight pruritus, which was less severe than formerly. Dysuria had not recurred. Skin pigmentation persisted, and the blood-pressure was 60/30 mm. Hg in each arm. Further investigations in February 1966 showed haemoglobin 12.4 g./100 ml.; E.S.R. (Westergren) 47 mm./hr.; blood urea 95 mg./100 ml.; plasma sodium 144 mEq/l.; potassium 3.4 mEq/l.; chloride 88 mEq/l.; bicarbonate 33 mEq/l.; serum calcium 9.3 mg./100 ml.; phosphate 4.6 mg./100 ml.; alkaline phosphatase 13 King-Armstrong units/100 ml.; serum albumin 4.5 g./100 ml.; globulin 2.8 g./100 ml. Mid-stream urine contained a trace of protein, a few R.B.C.s but no W.B.C.s, and was sterile on culture. Plain *x*-ray film of the abdomen showed no change in the size of the kidneys or in the degree of nephrocalcinosis compared with the 1963 films.

COMMENT

The term "milk-alkali syndrome" has been used to describe two separate conditions that may complicate treatment of peptic ulcer. Cope (1936) first reported hypercalcaemia, alkalosis, and temporary impairment of renal function, these abnormalities being corrected by stopping alkali therapy. Our case, however, is an example of the chronic form of milk-alkali syndrome in which renal function remains permanently impaired when alkalis are withdrawn. This condition was first described by Burnett *et al.* (1949), who described the occurrence of the following syndrome in six patients with a history of prolonged and excessive intake of milk and absorbable alkalis: hypercalcaemia without hypercalciuria or hypophosphataemia, normal serum alkaline phosphatase, marked chronic renal insufficiency with azotaemia, mild alkalosis, calcinosis manifested especially by an ocular lesion resembling band keratitis, and improvement in clinical state on a lowered intake of milk and absorbable alkali. Two of these patients had renal calcification. By 1963 Punsar and Somer were able to review 33 reported cases of irreversible renal failure due to prolonged excessive intake of absorbable alkali, associated in most but not all instances with excessive milk consumption.

Rifkind *et al.* (1960) reported the only previous British case that we have been able to find with the principal features of the chronic milk-alkali syndrome. Their patient was a woman of 48 who had taken 30 Rennies tablets daily for 10 years without excessive milk intake. Besides uraemia and nephrocalcinosis there were calcium deposits in the corneae and sclerae, aorta, and abdominal lymph nodes and there was generalized osteosclerosis, whereas our patient had radiologically normal bones. Our case, like theirs, had an excessive intake of calcium and absorbable alkali derived from Rennies tablets. In our patient the rapid fall in the serum calcium level with subsequent improvement in the general state of health and fall in blood urea after stopping the Rennies tablets indicates that they were the cause of the hypercalcaemia and nephrocalcinosis. The absence of further deterioration of renal function almost three years after stopping the tablets is noteworthy. Both our patient and that of Rifkind *et al.* took large quantities of Rennies tablets because they had developed a liking for them. It seems improbable that any patient would take so many antacid tablets solely to relieve dyspepsia.

We are grateful to Dr. J. D. N. Nabarro for advice. We wish to thank Dr. H. L. Marriott for permission to report this case.

Pernicious Anaemia and Intestinal Malabsorption: Spinal Cord Degeneration Developing during Vitamin B_{12} Treatment

Brit. med. J., 1967, **3**, 657–658

CASE REPORT

The patient was born in Northamptonshire in 1890 and emigrated to New Zealand at the age of 33. In 1927, when aged 37, she began to pass loose pale stools, about six daily. She complained of audible bowel sounds and of excessive flatus. When first seen by a physician she was aged 59 and considerably underweight. Severe macrocytic anaemia and a megaloblastic sternal marrow were present. Gastric analysis showed achlorhydria. Her pale stools, when dried, contained 32% by weight of fat. A barium enema was normal. Her blood picture quickly returned to normal after the twice-weekly injection of Anahaemin (liver extract) 2 ml. As diarrhoea continued in spite of a low-fat diet, folic acid 10 mg. b.i.d. was added, but was soon discontinued because her diarrhoea increased. Fortnightly injections of Anahaemin were continued, given by her general practitioner.

She was not seen again by a physician until the age of 66. Her blood was then normal, with a packed cell volume of 40%. Her stools were still pale and loose, and contained 36% by weight of fat. Her glucose tolerance curve was flat. A gluten-free diet was started and cortisone acetate 25 mg. was given by mouth twice daily. She improved in health, her diarrhoea diminished, and she was able to take a trip to the United Kingdom.

At the age of 69 she was still in good health, with one stool daily. Liver extract injections were then stopped, and vitamin B_{12} 200 μg., weekly at first and later fortnightly, was prescribed. The gluten-free diet and cortisone were continued.

At the age of 70 she was found on routine examination to have reduced vibration sense in both lower legs. Later in the same year she complained of unsteadiness of gait, and there was some oedema of both legs. Her blood count and serum proteins were normal.

The following year she became increasingly unsteady on her feet, especially when walking in the dark. She complained of weakness of her legs and of tingling burning sensations in both feet and to a lesser extent in her hands. Examination revealed a positive Romberg sign, an ataxic gait, and some impairment in her legs of all sensory modalities, especially vibration and postural sensibility. Both knee and ankle jerks were abnormally brisk and the plantar reflexes were extensor. The clinical picture was that of subacute combined degeneration of the cord with mild peripheral neuritis.

In view of this development the vitamin B_{12} dosage was increased to 200 μg. twice weekly and she was admitted to hospital for reassessment. Repeated peripheral blood counts and a sternal marrow examination were normal. Repeated serum vitamin B_{12} levels were well within the normal range—namely, 460 and 480 $\mu\mu$g./ml. (normal 150–650). Her serum folic acid was 8 mμg./ml. (normal 5–16). Augmented histamine stimulation failed to provoke any gastric secretion of hydrochloric acid. Absorption of cobalt-labelled vitamin B_{12} (Schilling test) was grossly defective. This absorption test was repeated after the administration of

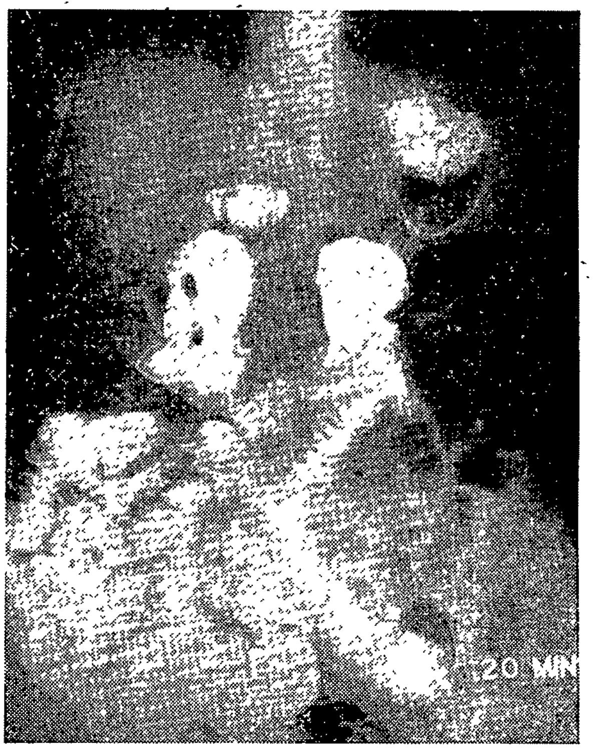

FIG. 1.—Barium-meal examination showing multiple small-bowel diverticula.

intrinsic factor, and though there did seem to be slight improvement this was not thought to be significant. A xylose-absorption test gave an abnormally low result. Her renal function was normal.

A barium-meal examination showed three large diverticula of the duodenum and numerous smaller ones of the proximal jejunum. In the lower jejunum and ileum the barium became flocculated with a typical malabsorption pattern which made demonstration of diverticula impossible in this region.

She was given a prolonged oral course of tetracycline without obvious clinical improvement. Vitamin B_{12} 200 µg. was administered thrice weekly and her serum B_{12} level rose to 1,080 µµg./ml. In addition thiamine hydrochloride 100 mg. was given intramuscularly each day. As there was no obvious improvement in her condition vitamin B_{12} was later discontinued and a change made to Neo-hepatex 2 ml. twice weekly for a period of eight months. There was still no obvious improvement, so the frequency of administration was reduced to once a week and eventually to once a fortnight.

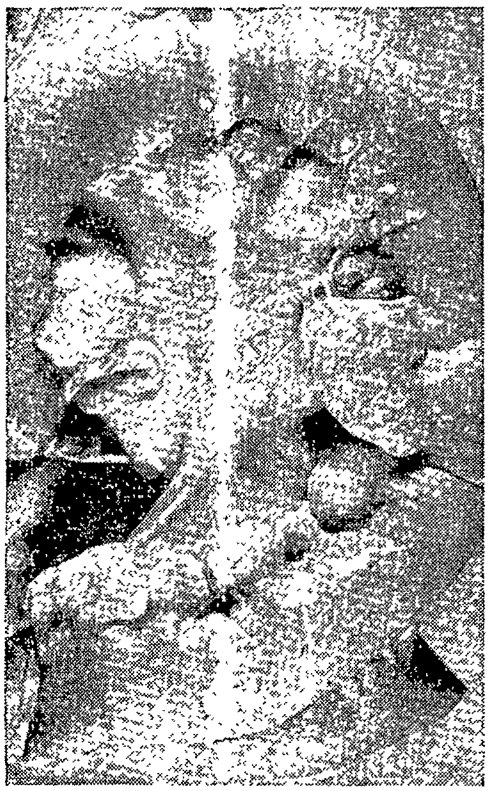

FIG. 2.—Necropsy specimen of small bowel showing diverticulosis.

By this time she was leading a wheel-chair existence because of her ataxia and weakness. Her nervous system signs remained much the same, except that her ankle reflexes were now less brisk than her knee reflexes. She remained in this state, with little progression, during the next four years, and throughout this time she was mentally alert. She then had an attack of persistent vomiting and was admitted to hospital in a state of shock. Her abdomen was distended, and bowel sounds were diminished, though there was an absence of pain or tenderness. Colon bacilli were cultured from her blood. In spite of intensive restorative measures she died. She was then aged 76.

Necropsy Report.—Stomach: thin-walled. Duodenum: three large diverticula of the second part. Jejuno-ileum: numerous large, wide-mouthed, slightly loculated mesenteric diverticula gradually diminishing in number and size to the mid-gut, but still present though smaller, to the terminal ileum ; ulceration of Peyer's patches in lower end of ileum, one of them on the point of perforation. Brain: weight 920 g.; considerable gyral atrophy with focal atrophy of the cerebellum. Spinal cord: general atrophy. Bones: well-marked vertebral osteoporosis.

Microscopical Findings.—Stomach: complete gastric atrophy with reversion to a "colonic" type of mucosa ; muscle also thin. Jejuno-ileum: villous structure preserved. Liver: fatty change associated with peliosis. Brain: no gross neuronal "fall-out" in cortex or brainstem nuclei. Spinal cord: degeneration of dorsal and lateral columns typical of subacute combined degeneration.

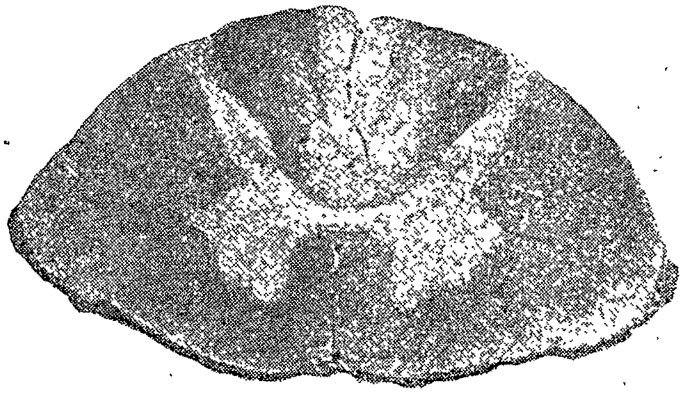

FIG. 3.—Section of spinal cord showing dorsal and lateral tract degeneration.

COMMENT

This unusual case in which symptoms and signs of spinal cord degeneration appeared while the patient was receiving adequate parenteral vitamin B_{12} or liver extract was about to be reported when Ellis, Breuer, Owen, and Laszlo (1966) reported a similar experience. In the present case, however, the clinical findings were supported by post-mortem examination.

This patient undoubtedly suffered from pernicious anaemia. In addition, there was evidence of intestinal malabsorption apparently related to her extensive small-bowel diverticulosis. Subacute combined degeneration progressed in spite of an increase in dosage of vitamin B_{12} and also of a reversion to liver extract. Serum vitamin B_{12} was normal at a time when her condition was progressing and there was no improvement even when her serum B_{12} level was raised to twice normal levels.

It would appear, therefore, that here as in the case reported by Ellis *et al.* (1966) the patient's nervous system was unable to utilize vitamin B_{12}.

I am grateful to the medical superintendent, Christchurch Hospital, Dr. W. I. Paterson, for permission to publish this case and to the director of pathology, Dr. D. T. Stewart, and the assistant radiologist, Dr. R. H. Gibson, for their help.

Irreducible Posterior Dislocation of the Elbow

Brit. med. J., 1967, **3**, 659

All published reports on posterior dislocation of the elbow are concerned with old dislocations (Vangorder, 1932 ; Allende and Freytes, 1944), disclocations associated with fracture of the medial epicondyle with displacement into the joint (Roberts, 1934 ; Outland and Hanlon, 1938 ; Patrick, 1946 ; Smith, 1950 ; Purser, 1954), dislocation associated with rupture of the brachial artery (Spear and Janes, 1951 ; Henderson and Robertson, 1952), dislocation complicated by ulnar nerve injury (Outland and Hanlon, 1938), and recurrent dislocations of the elbow (Milch, 1936 ; Reichenheim, 1947 ; Wainwright, 1947 ; Kapel, 1951 ; King, 1953 ; Spring, 1953 ; Osborne and Cotterill, 1966). However, a search of the literature from the English-speaking world has not revealed any reported case where there was failure to reduce an uncomplicated posterior dislocation of the elbow by manipulation under anaesthesia soon after injury. This must be extremely uncommon. This report describes such a case.

CASE REPORT

A girl aged 7 years was seen with an injury to her left elbow after a fall on her outstretched hand. On examination the elbow was deformed and there was no bruising or swelling around that joint. There was no nerve or vascular injury. *X*-ray examination of the elbow showed posterior dislocation without fracture.

Three hours after the injury the elbow was manipulated under general anaesthesia, but the dislocation could not be reduced despite a further attempt later. Even at this stage the elbow did not show any bruising or swelling. Because of the absence of bruising and swelling an old dislocation of the elbow was considered, but the patient was very intelligent and maintained that the left elbow was normal before the fall. Open reduction was undertaken the following day.

Operation.—Initially, the elbow was explored through a medial vertical incision. There was no bruising in the soft tissues. The medial ligament and the medial epicondyle were normal. A posterolateral incision was made and the head of the radius was found dislocated through a small buttonhole tear in the posterolateral capsule of the joint. The proximal ulna was found dislocated posteriorly without any tear in the capsule. On attempting reduction the buttonhole in the capsule tightened around the narrow portion of the neck of the radius and prevented reduction. After enlarging the buttonhole the dislocation was reduced quite easily. The orbicular ligament was found intact.

Postoperative progress was normal and the elbow was immobilized for three weeks. Two months later the elbow movements were satisfactory except for the last few degrees of extension.

COMMENT

It is quite evident in this case that closed reduction failed because the head of the radius had passed through a small tear in the posterolateral capsule and the buttonhole effect tightened around the narrow portion of the neck of the radius. When traction was applied in the line of the deformity the buttonhole tightened and prevented reduction of the dislocation. Once the buttonhole was enlarged the reduction was very easy.

Another interesting feature in this case is that there was no bruising or swelling—a feature sufficient to make one consider the possibility of an old injury. One would expect some bruising and swelling on the medial side of the joint in a recent dislocation of the elbow. In this case the medial ligament would have been stretched and not torn. The torn blood vessels in the buttonhole tear in the capsule did not bleed, probably because the vessels were compressed by the neck of the radius or because displacement was so minimal.

I wish to thank Mr. E. J. Hargadon for permission to publish this case and for his helpful criticism.

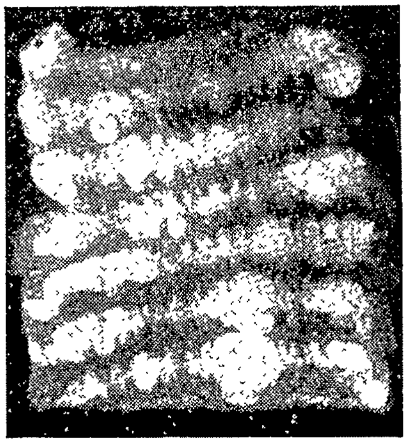
Human Infection with a Tapeworm, Bertiella sp., probably of African origin

Brit. med. J., 1967, **3**, 659–660

Proglottides of a tapeworm were passed intermittently for six months in the faeces of a British boy aged 6 who was otherwise well and had no complaint of bowel disturbance. He had lived in Aden for the previous two years. The proglottides proved to be terminal segments of *Bertiella* sp. Identification to species was not possible. The boy was successfully treated with niclosamide (Yomesan).

Bertiella is normally a parasite of monkeys. On further inquiry it was found that nearly two years previously the boy had spent a fortnight's holiday in Mombasa, East Africa, where he had close contact with monkeys ; these were thought to be of the rhesus type and were tame enough to be fed by hand.

The life history of *Bertiella studeri* (Blanchard, 1891), which is the principal species of the Eastern Hemisphere, was elucidated by Stunkard (1940) ; he fed eggs of the tapeworm experimentally to various free-living mites and later found cysticercoids (the infective stage for the final, definitive host) in the



Segments of *Bertiella* sp. tapeworm. (×5.)

body cavity of some of the mites. Presumably, human infection results from the accidental ingestion of infected mites.

This is the twenty-fifth report of human infection with bertiella. Geographically, these reports are mainly from the Eastern Hemisphere—namely, Mauritius (4), India (8), Sumatra (1), Java (2), Borneo (1), Philippines (1), Singapore (1), East Africa (1). In the Western Hemisphere it has been reported once from Cuba, St. Kitts (West Indies), Brazil, Argentina, and Paraguay. The present case is of interest in that the infection was probably acquired in Africa, whence only one case has previously been recorded (Buckley and Fairley, 1950), and in that from the available evidence the boy had probably harboured the worm for about two years.

The subject of bertiella infection to man has been recently reviewed by D'Alessandro, Beaver, and Pallarés (1963).

We are indebted to Mr. S. Nicholson for the preparation of the specimen and to Dr. M. R. Thomas for the photograph.

Self-poisoning with Digoxin: Successful Treatment with Atropine

Brit. med. J., 1967, **3**, 660–661

Self-poisoning with digitalis is uncommon. Lethal doses are massive (McGuire and Richards, 1936; Bergy *et al.*, 1957; Johnston and Price, 1960), and death is more likely to follow the ingestion of digitoxin than the more rapidly excreted digoxin. Recovery after very large doses of digoxin (Bernstein *et al.*, 1959) and digitoxin (Bergy *et al.*, 1957; Knowles, 1959) has been reported, and it is apparent that survival is more likely when the myocardium is healthy.

CASE REPORT

A housewife aged 52 with a long history of depression started taking digoxin in 1961 for lone atrial fibrillation. At 11 a.m. on 18 October 1965 she took 6.25 mg. of digoxin. On admission to another hospital the pulse rate was 40 a minute and the blood pressure 90/40 mm. Hg; vomiting and diarrhoea decreased after chlorpromazine (100 mg. intramuscularly). On 19 October the pulse rate was 22–25, and she was transferred to the London Chest Hospital.

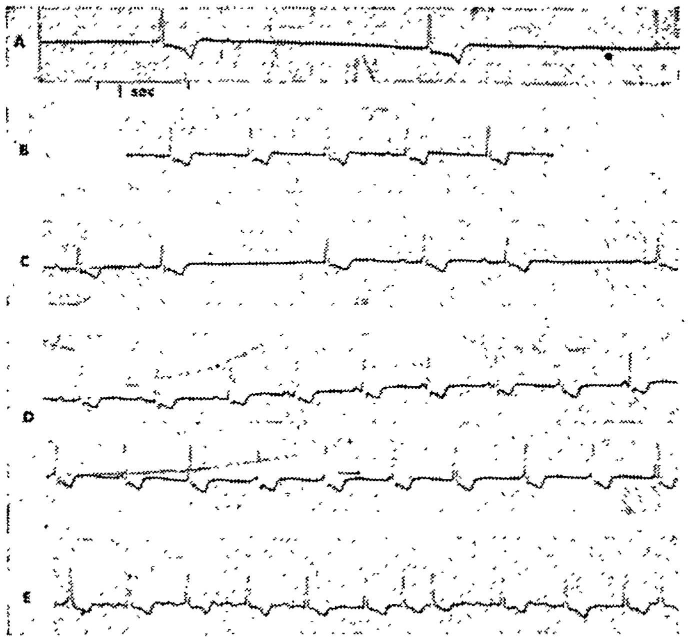
She was drowsy and pale, with cold extremities. The pulse was regular at 15, and the blood pressure 120/60. There was slight hepatomegaly, but no other evidence of congestive cardiac failure. She had profuse cold sweats. An electrocardiogram (see Fig., A) showed no atrial activity; the ventricular rhythm was regular, with normal QRS complexes. Serum potassium was 7.9 mEq/l. and blood urea 61 mg./100 ml.

While preparations were being made to insert an electrode pacemaker catheter it was decided to try the effect of atropine. Atropine (0.6 mg.) was given intravenously; the pulse rose to 60/min. within 20 minutes, but then slowed to 36/min. during the next 20 minutes. Atropine (0.6 mg. intravenously) was repeated, and the rate increased to 72. The electrocardiogram (see Fig., B) showed sinus rhythm, with low-voltage P waves and constant long P–R interval (0.24 sec.). Whenever the heart rate fell below 50, atropine (0.6 mg.) was given intramuscularly; she needed an injection about every five hours for the first 36 hours. During this time the electrocardiogram showed an irregular bradycardia, with variable long P–R interval (0.24–0.30 sec.), and variable P wave morphology (see Fig., C); one tracing after atropine showed atrioventricular dissociation (see Fig., D). On 22 October she reverted to atrial fibrillation, with irregular ventricular response (see Fig., E) and was put back on digoxin.

On admission, she had been anuric for over 24 hours. An intravenous drip (5% dextrose) was started, with added sodium bicarbonate; 20% mannitol was also given (total 300 ml. in 14 hours), and urine flow was re-established within half an hour. After an initial rise to 150 mg./100 ml. the blood urea rapidly fell to normal; the serum potassium also fell, to 4.2 mEq/l., and potassium by mouth was started after 18 hours.

She rapidly became more responsive, but remained seriously depressed, and was discharged for further psychiatric treatment after 10 days.

Liver-function tests initially gave abnormal results (21 October: S.G.O.T. 130 units/ml.; S.G.P.T. more than 160 units/ml. 27 October: sulphobromophthalein excretion test: 47% retention at 25 minutes, and 30% retention at 45 minutes) but later returned to normal.



Serial electrocardiograms (all lead II). A, 19 October, before treatment: sinus arrest; extreme nodal bradycardia. B, 19 October, after intravenous atropine: sinus rhythm; low-voltage P waves; long P–R interval. C, 20 October: wandering pacemaker. D, 20 October, after atropine: two consecutive strips showing atrioventricular dissociation. E, 22 October: atrial fibrillation.

DISCUSSION

The toxic effects of digitalis on the heart have been well reviewed by Burwell and Hendrix (1950), Lown and Levine (1954), Schott (1964), and Dubnow and Burchell (1965). A regular rhythm may occur in the presence of atrial fibrillation as a result of digitalis-induced complete heart block, when the ventricles are controlled by a pacemaker in the main bundle or atrioventricular node below the level of the block; a nodal rhythm may also be associated with atrioventricular dissociation. Sinuatrial block, "wandering pacemaker," and sinus arrest are rare, but were reported by Burwell and Hendrix (1950), and by Bernstein *et al.* (1959) and Knowles (1959) in their cases of massive overdose. In our patient there was atrial asystole with profound slowing due to depression of the nodal pacemaker. Neither ventricular ectopic beats nor paroxysmal atrial tachycardia with block was seen, but may have been prevented by the high serum potassium; Lown and Levine (1954) observed that ectopic beats were rare in digitalis poisoning in patients without heart disease. Hyperkalaemia was probably due to anuria, metabolic acidosis, and the efflux of potassium from the myocardium which occurs with toxic doses of digitalis.

The treatment of digitalis intoxication is based on the withdrawal of digitalis, correction of potassium depletion, and specific measures directed against the arrhythmia (Lown and Levine, 1954; Sodeman, 1965). Sampson *et al.* (1943) abolished digitalis-induced ventricular ectopic beats with potassium salts given by mouth. Procainamide and beta-adrenergic blocking agents (Stock and Dale, 1963; Taylor *et al.*, 1964) have been successfully used for digitalis-induced paroxysmal atrial tachycardia with block and ventricular ectopic beats. Calcium ions potentiate digitalis action, and the chelation of calcium with disodium versenate has been recommended by Gubner and Kallman (1957) and Bernstein *et al.* (1959) in cases of digitalis overdosage.

In our case the blood pressure was well maintained, suggesting that myocardial contractility was not depressed, and that the low cardiac output was due mainly to bradycardia. Atropine was tried as it seemed likely that the extreme bradycardia was due to excessive vagal depression of the nodal pacemaker. It is well known that slowing of the ventricular rate in atrial fibrillation by digitalis is partly mediated by the vagus, though with larger doses the extravagal effect on atrioventricular conduction is more important, so that atropine is relatively ineffective in increasing the ventricular rate (Gold, 1946). In our case, though the dose was massive, the response to atropine was dramatic, but repeated injections were required to maintain a satisfactory heart rate. The nodal rhythm was replaced by a sinus mechanism or wandering pacemaker, and at this stage atropine increased the rate of discharge of both the sinuatrial and the atrioventricular node, with periods of atrioventricular dissociation.

Digitalis is excreted mainly by the kidney (Friedman *et al.*, 1954), small quantities being destroyed in the body or excreted in the bile. Prompt restoration of urine flow was thus very important in clearing digoxin from the body.

Impaired liver function in patients with heart disease may be due to hypotension or cardiac failure (Killip and Payne, 1960; Richman *et al.*, 1961) but may be caused by digitalis itself. Le Winn (1953) found impaired sulphobromophthalein excretion in patients with gynaecomastia, which was attributed to an oestrogenic effect of long-continued digitalis administration in patients with liver damage. In our patient raised transaminases and increased sulphobromophthalein retention probably resulted from reduced hepatic blood flow, but direct injury by digoxin cannot be ruled out.

We are indebted to Dr. H. G. L. Lloyd-Thomas, who referred this patient to us.

Self-poisoning with Digitalis Glycosides

Brit. med. J., 1967, **3**, 661–662

Digitalis and its crystalline derivatives are seldom used in suicidal attempts. Moore (1937) reviewed 1,147 cases of attempted suicide; poisons were taken in 692 cases, but only one patient used digitalis. Of 16 previously reported cases of self-poisoning by digitalis (McGuire and Richards, 1936; Tomaszewski and Lapa, 1936; Moore, 1937; Duvoir *et al.*, 1938; Bickel *et al.*, 1951; Vuletic and Ivancic, 1952; Yu, 1954; Bergy *et al.*, 1957; Von Oettingen, 1958; Segre, 1959; Bachmann, 1960; Bernot and Goldberg, 1960; Johnston and Price, 1960; Aubertin *et al.*, 1961; Thomopoulos and Kokkinos, 1965) only three were fatal (McGuire and Richards, 1936; von Oettingen, 1958; Johnston and Price, 1960).

The present report describes two patients who poisoned themselves with digitoxin and digoxin respectively, adding one to this very small number of recorded fatal cases.

CASE 1

A man, aged 59, was brought to the Victoria Infirmary, Glasgow, at 9.30 p.m. on 17 June 1964. Six hours previously he had swallowed 100 tablets (10 mg.) of digitoxin, prescribed for his deceased wife. Since her death he had been depressed and had had epigastric discomfort but no other somatic symptoms. There was no history of cardiac or vascular disease.

He was a small thin man, drowsy but in no way distressed. There were no congestive signs or cyanosis. Blood pressure was 100/70. Cardiac rhythm was totally irregular with a ventricular rate of 44 per minute. The heart was not enlarged; sounds were normal except for a very soft, short systolic murmur localized to the apex. There were no significant abnormalities in other systems. An electrocardiogram taken shortly after admission showed atrial fibrillation and ST–T segment changes in keeping with digitalis effect.

Gastric aspiration yielded no tablets or particles. At 10 p.m. he was given ephedrine 60 mg. and potassium chloride 6 g. by mouth. At 11 p.m. the heart rate was about 50. Atropine sulphate 0.5 mg. was injected subcutaneously. His general condition remained satisfactory until just after midnight, when he suddenly collapsed in coma. He died about 45 minutes later. Electrocardiograms (lead I) were recorded during this period (see Fig.).

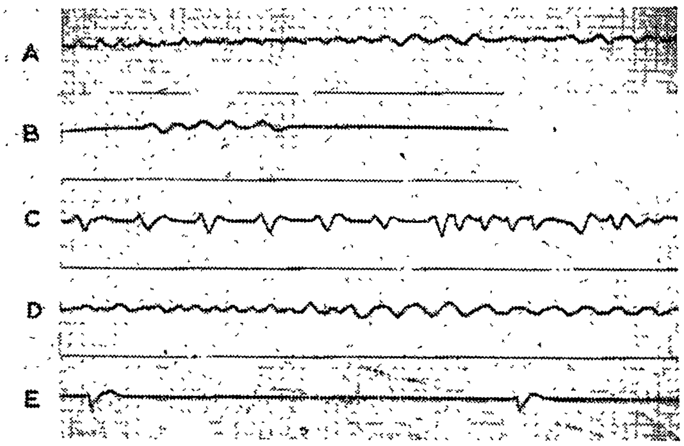
Permission for necropsy was not granted

CASE 2

A man, aged 22, had rheumatic mitral and aortic valve disease with atrial fibrillation. He had been taking digoxin 0.25 mg. twice daily for at least seven years. He had been depressed for several weeks on account of increasing cardiac disability. On the evening of 13

January 1966 he drank some alcohol and swallowed between 16 and 20 tablets (4–5 mg.) of digoxin. He developed headache, giddiness, and nausea but did not have abdominal pain. He was given saline to drink by his family doctor and vomited.

On admission to Stobhill Hospital, Glasgow, early on the morning of 14 January he was fully conscious but depressed. His general condition was good. Blood pressure was 125/65. Cardiac rhythm was totally irregular with a ventricular rate of 60. The heart was considerably enlarged with signs of double mitral and aortic valve lesions. There were no congestive signs. No abnormalities were found in other systems.



CASE 1.—Electrocardiogram (lead I) after collapse. A (at 12.05 a.m.) shows ventricular fibrillation. B (at 12.20 a.m.) shows ventricular fibrillation and periods of cardiac asystole. C and D (continuous) (at 12.30 a.m.) show idioventricular rhythm with a brief episode of ventricular tachycardia followed by ventricular fibrillation. E (at 12.40 a.m.) shows very slow idioventricular rhythm, which led to final cardiac asystole.

Gastric lavage yielded no tablets or particles. Heart rate fell to 40 and rhythm remained irregular. He was given propranolol 10 mg. intravenously without significant effect. After a further slight decrease in heart rate atropine sulphate 0.5 mg. was injected with little effect. Heart rate was 42 eight hours after admission. Subsequent clinical progress was uneventful and bradycardia disappeared within a few days. By 20 January the electrocardiogram showed no clear evidence of digitalis toxicity and the heart rate was 75. On 24 January the previous maintenance dose of digoxin was resumed without ill effect.

DISCUSSION

Treatment of Digitalis Poisoning.—Digitalis has its most toxic effect on the heart, probably related to a shift of potassium from the myocardium (Calhoun and Harrison, 1931). To some extent this may be counteracted by the administration of potassium (Kay, 1955), which was given to Case 1. In animals, digitalis derivatives may cause focal myocardial necrosis (Dearing *et al.*, 1943) possibly owing to vagal stimulation, since atropine can prevent its occurrence (Kyser *et al.*, 1946). Myocardial necrosis ascribed to digitoxin poisoning in man was recorded by Johnston and Price (1960). Atropine was therefore given in both the above cases. Propranolol was given in Case 2 to avert the possible onset of serious arrhythmias. Vaughan Williams and Sekiya (1963) proposed beta sympathetic blockade as an antidote in glycoside intoxication. This measure may be required to maintain sinus rhythm after abolition of digitalis-induced ventricular fibrillation by direct current countershock (Sloman *et al.*, 1965). A combination of all these measures with monitoring in a coronary care unit might prove life-saving in digitalis poisoning, whether suicidal or otherwise.

Digitalis and the Electrocardiogram.—The characteristic effects of digitalis on the electrocardiogram—depression of the S–T segment, shortening of the Q–T interval, and inversion of the T wave (Wood, 1956)—were observed in the electrocardiograms of both cases shortly after admission. In Case 1 digitoxin poisoning presumably caused atrial fibrillation, but in Case 2 it had existed for several years. Digitalis may provoke almost any cardiac arrhythmia. Ventricular tachycardia and fibrillation were observed in Case 1 in addition to very slow idioventricular rhythm (see Fig.). The tracings closely resemble those of patients dying suddenly from myocardial infarction. The heart often shows electrical activity with slowing idioventricular rhythm after apparent clinical death (Stroud and Feil, 1948). This terminal rhythm does not seem to have been reported previously in connexion with digitalis overdosage.

Organic Heart Disease and Self-poisoning with Digitalis.—There have been only three previous reports of successful suicide with digitalis derivatives (McGuire and Richards, 1936 ; von Oettingen, 1958 ; Johnston and Price, 1960). In none of these cases and in few of the documented non-fatal cases was there clear evidence of pre-existing heart disease. This can also be said of the fatal case now reported.

I am grateful to Dr. Ian Murray and Dr. A. S. Rogen for permission to publish these cases and to Dr. T. Semple for helpful advice in the preparation of the paper.

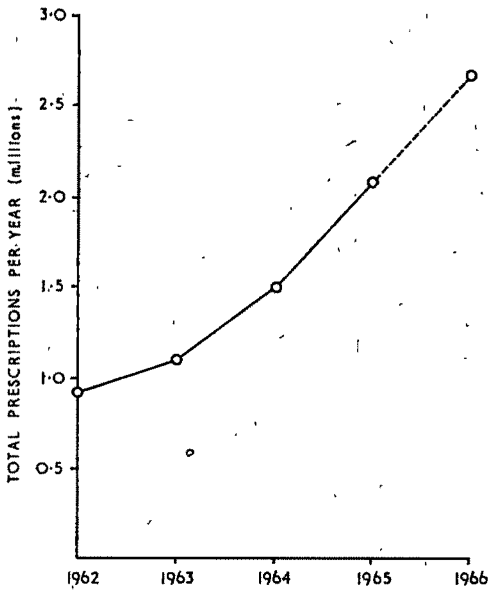
FORENSIC MEDICINE AND TOXICOLOGY

Clinical Effects and Treatment of Imipramine and Amitriptyline Poisoning in Children

C. M. STEEL,*† M.B., CH.B., B.SC. ; J. O'DUFFY,* M.B., B.S., M.R.C.P.ED. ; S. S. BROWN,‡ PH.D., B.SC.

Imipramine and amitriptyline are tricyclic antidepressant compounds whose chemical structure, dosage, pharmacology, and toxicity are so similar that they are commonly considered together (Klerman and Cole, 1965 ; Giarman, 1965 ; Rasmussen, 1965, 1966).

The danger to children of accidental ingestion of these drugs has become increasingly recognized in recent years (Noack, 1960 ; Giles, 1963 ; Sunshine and Yaffe, 1963), and at least 21 such accidents, including five deaths, have been reported. The main features of these reports are summarized in the accompanying Table.



Annual number of N.H.S. prescriptions of imipramine + amitriptyline in Great Britain 1962–6. The 1966 figure is predicted from data for the first six months.

During 1966 seven children were admitted to the medical wards of the Royal Hospital for Sick Children, Edinburgh, with a diagnosis of imipramine or amitriptyline overdosage. Over the preceding two-year period five similar cases were seen, but none was recorded before 1964. This suggests a trend which is entirely in keeping with the prescription rates for these two compounds in Great Britain as shown in the Chart (data supplied by the Ministry of Health). There is therefore reason to believe that from being an alarming but rare event, poisoning of children by these two drugs may become an increasingly common problem.

The purpose of this paper is to record the characteristic features of both mild and severe imipramine or amitriptyline poisoning and to derive a rational scheme of management based on a consideration of the pharmacology of these drugs, on a review of the literature, and on our own experience in practice.

Clinical Features of Mild Poisoning

Ten of our patients (all except Cases 26 and 31) and four of those previously reported (Cases 7, 8, 9, and 10) showed the symptoms of mild poisoning only. Some depression of consciousness was almost invariably seen, while six showed ataxia or a disturbance of posture out of proportion to their drowsiness. A striking feature in five of the children was the extreme agitation with which they responded to any stimulus, or which appeared spontaneously, alternating with periods of drowsiness.

Tachycardia, persisting during sleep, was present in 10 of these children, but none developed arrhythmia or hypotension, and electrocardiograms recorded in Cases 32 and 33 showed sinus tachycardia, with normal complexes. Some degree of pupillary dilatation was noted in four of the patients, while thirst, dizziness, nystagmus, or vomiting was occasionally apparent.

These symptoms tended to develop gradually within one to four hours of ingestion of the drug. Paraldehyde was given to control restlessness in one (Case 8), but all the others recovered spontaneously and completely within 24 hours.

One patient (Case 28) did not develop symptoms of poisoning, and may not in fact have swallowed any drug, though he was found with several tablets in his mouth and surrounded by many more from which he had sucked the sugar coating.

Clinical Features of Severe Poisoning

Severe poisoning is characterized by the development of convulsions and coma ; in addition, severe respiratory depression, cardiac arrhythmias, E.C.G. changes, and profound hypotension may occur. The detailed clinical features are best described by a case report.

Case 31

A previously healthy boy of 5 years 4 months was observed to become grossly ataxic over a period of a few minutes. He seemed to be unaware of his surroundings, and within 15 minutes lapsed into coma and had a generalized tonic-clonic seizure. During the journey to hospital of 45 minutes, almost continuous twitching of the limbs was observed and on arrival he was deeply unconscious. Any form of stimulus, such as the aspiration of pharyngeal secretions, provoked a generalized convulsion lasting some 30 seconds.

* University Department of Child Life and Health and Professorial Unit, Royal Hospital for Sick Children, Edinburgh.

† Present address: Department of Medicine, Western General Hospital, Edinburgh.

‡ University Department of Clinical Chemistry, Royal Infirmary, Edinburgh.

On examination there were no localizing signs. Tone and deep tendon reflexes were normal and the plantar responses were flexor. The pupils were dilated equally and responded sluggishly to light (within one hour they became widely dilated and fixed); the fundi appeared normal and there was no meningism. The boy's temperature was normal, his colour good, and respirations were 24/min., regular but shallow. The apex rate was 148/min. and regular. Peripheral pulses were of good volume and the arm blood pressure was 115/70 mm. Hg.

Estimates of blood glucose, plasma calcium, urea, and electrolytes gave normal values, and lumbar puncture yielded clear cerebrospinal fluid under normal pressure with normal glucose and protein concentrations.

After passage of a cuffed endotracheal tube, gastric lavage was performed and the stomach content (which contained no visibly identifiable remnant of tablets) kept for examination.

Paraldehyde (5 ml. intramuscularly) was given to control convulsions, and thereafter he became completely unresponsive even to painful stimuli.

The parents at first insisted that the child could have had access only to a salicylate preparation (Palaprin), but on persistent questioning they recalled that a bottle of grandmother's "nerve tablets" were kept on top of the wardrobe. These were said to be Triptafen tablets, each containing amitriptyline (25 mg.) and perphenazine (2 mg.).

The presence of amitriptyline (though not of perphenazine) in the gastric aspirate was quickly established and a conservative policy of management adopted. Slow intravenous infusion of 5% dextrose in half-strength Ringer's lactate was started. Pulse rate, blood pressure, respiratory rate, pupil size, and conscious level were recorded every 15 minutes and rectal temperature every two hours. Over the next 24 hours the blood pressure fluctuated between 110/70 and 90/60 mm. Hg. Tachycardia persisted, the apex rate reaching 160/min., but no irregularity was detected and the peripheral pulses remained easily palpable.

The level of consciousness rose steadily. Sixteen hours after the estimated time of ingestion of the tablets the endotracheal tube was removed because of gagging, and shortly afterwards the child opened his eyes. His reactions to stimuli then became more vigorous, and by 24 hours he responded to any interference with grossly exaggerated movements of the limbs and signs of great agitation. This was controlled by intramuscular chlorpromazine (25 mg.), a total of four doses being required at intervals of 4, 6, and 13 hours.

No urine was passed spontaneously for the first 24 hours though the bladder became readily palpable above the pubic symphysis. The child's rectal temperature rose to 38.3° C. (101° F.) at 36 hours, but by then there was evidence of a basal pneumonia, which complicated his recovery.

Forty-eight hours from the time of ingestion he recognized his parents and was able to drink from a cup. By 60 hours he was entirely rational with no evidence of neurological deficits, and after a course of antibiotics and physiotherapy he left hospital on the eighth day.

TABLE

Case No.	Author	Age in Years	Drug(s)	Dose (mg.)	Dose (mg./kg. Body Weight)*	Levels (μg./100 g.)	Symptoms and Signs	Treatment	Outcome
1	Noack	2 6/12	Imipramine	2,500	(192)	Liver, 2,700	Coma, continuous convulsions, cyanosis, dilated pupils, cardiac and respiratory arrest	Gastric lavage, artificial respiration, cardiac massage	Died

* Figures in parentheses indicate that calculation is based on average weight for age, where actual weight was not recorded.

(*Continued on next page*)

When discharged from follow-up two months later he was well in all respects, and had resumed normal school activities. He was indeed able to give a full account of having found the tablets, swallowed them all (between 55 and 60), and discarded the empty bottle. His first symptoms had developed some 45 minutes later.

Toxicology

The suggestion of salicylate poisoning in the above case was discounted both on clinical grounds and in view of the fact that side-room testing for plasma salicylate (Brown *et al.*, 1967) yielded negative results. In formally excluding this possibility by spectrophotofluorometric assay of the blood, evidence suggesting the presence of a phenothiazine derivative or a tricyclic antidepressant was found. Concurrently, the appropriate history was obtained. Amitriptyline was then identified and assayed in the gastric aspirate by extraction at alkaline *p*H with heptane, back extraction into acid, and ultra-violet spectroscopy. While the recovery was only 30 mg., it should be emphasized that, in general, gastric washings represent the most suitable clinical material from which to make positive identification of an ingested drug, since metabolic change is minimal and the actual concentration may be higher than in any other available body fluid, particularly if aspiration has been carried out within a short time of ingestion.

The estimation of plasma amitriptyline by a fluorometric method analogous to that used by McBay and Algeri (1963) for imipramine gave a level of 700 µg./100 ml. for the blood sample drawn five hours after ingestion, when absorption would have been virtually complete. This represents a level of about 20 times that obtained in adults on therapeutic doses, and considerably exceeds levels found in the fatal cases of Sunshine and Yaffe (Case 14) and Dingell *et al.* (1964) (Case 18). It is unfortunate that such determinations have been made so rarely in these cases, since the peak blood level represents a valuable measure of the degree of overdosage, in addition to providing confirmation of the identity of the drug in question.

Only 13 mg. of amitriptyline was recovered from the urine passed during the first 48 hours after ingestion. Attempts to establish the presence of perphenazine in this specimen or in gastric aspirate or blood were unsuccessful even when the sensitive and specific method of Ragland *et al.* (1965) was used.

Discussion

From the data in the Table some quantitative assessment of the toxicity of imipramine and amitriptyline to children can be made. The severe symptoms described may be precipitated by the ingestion of less than 10 mg./kg. (Cases 11 and 19), and seem inevitable when the dose exceeds 20 mg./kg. In practical terms the latter figure means, for a 2-year-old, 10 standard tablets of either drug, or one bottle of amitriptyline paediatric elixir (usually prescribed for the treatment of functional nocturnal enuresis).

The smallest fatal dose in a child was 32 mg./kg. (Case 12) and the largest amount taken by one who survived was 112 mg./kg. (Case 3). This variation in susceptibility parallels experi-

* Figures in parentheses indicate that calculation is based on average weight for age, where actual weight was not recorded.

ence in adults, death having been recorded after ingestion of only 625 mg. (9 mg./kg) (Edwards, 1966), but survival after as much as 5.5 g. (80 mg./kg.) (Harthorne *et al.*, 1963).

Of the five deaths among these children, one patient (Case 1) who had ingested 192 mg./kg., was moribund within one hour and failed to respond to vigorous resuscitation. One (Case 18) died three days after ingestion, but no further details are recorded, while the timing of death from cardiac arrest in Case 17 is not reported. Cases 12 and 14 are noteworthy in that both had shown progressive clinical improvement, in terms of conscious level and circulatory status, before sudden collapse and death 12 and 60 hours respectively from the time of ingestion of the drug.

Treatment

On the wide variety of measures which have been used in the management of children or adults poisoned by tricyclic antidepressants, only a minority stand out as being both clinically effective and pharmacologically sound.

Active Therapy

Since there is often some delay in confirming the identity of the drug involved, gastric lavage should be carried out as soon as the child reaches hospital ; the general recommendations of Matthew *et al.* (1966) in relation to gastric lavage in adults are applicable also to paediatric practice. In Case 31 little over 2% of the estimated ingested dose was recovered from the stomach, but when the procedure is carried out very soon after ingestion recovery of some 15% may be achieved (Rasmussen, 1966). If the accident is detected within minutes, induction of vomiting by the parents or the general practitioner may be a useful measure, provided that transfer of the child to hospital is not thereby delayed.

Both peritoneal and extracorporeal dialysis have proved ineffective in the treatment of this type of poisoning (Sunshine and Yaffe, 1963 ; Harthorne *et al.*, 1963). Moreover, our own measurements confirm previous indications that renal excretion of the free drug is so low that forced diuresis is not indicated (Hucker and Porter, 1961 ; Sunshine and Baumler, 1963), though this procedure has been advocated by Prout *et al.* (1965) on the strength of a positive result from a sensitive screening test for the detection of imipramine metabolites in the urine (Forrest *et al.*, 1960). The pharmacological activity of such metabolites is, however, unknown, whereas the *N*-desmethyl derivatives of both imipramine and amitriptyline, which are known to be active, are firmly tissue-bound (Dingell *et al.*, 1964). Beighton and Hardingham (1966) recovered at most 10% of the ingested dose of amitriptyline from the urine of their patient, measurement again being based upon a relatively non-specific test.

Supportive Therapy

Both barbiturates and paraldehyde are effective for controlling convulsions in severe antidepressant poisoning, and the former in particular are recommended by Rasmussen (1965). However, the respiratory depression induced by barbiturates may be potentiated in this situation (Luby and Domino, 1961 ; Arneson, 1960 ; Garrison and Moffitt, 1962 ; Merck, Sharp and Dohme, 1963). This disadvantage does not seem to apply to paraldehyde ; for example, the most severely poisoned of the present series (Case 31), who had a respiratory minute volume of 2.2 litres by direct spirometry on admission—that is, 20% below the ideal basal level, on the criteria of Radford (1955) —required no oxygen or assisted ventilation after 5 ml. of intramuscular paraldehyde.

Circulatory collapse is potentially the most dangerous consequence of imipramine or amitriptyline poisoning. Cairncross and Gershon (1962) and Boissier *et al.* (1965) have shown, in animal experiments, that whereas the initial tachycardia is mediated by an atropine-like vagal blockade larger doses of either drug have direct toxic effects upon the myocardium and conducting tissue. This can result in profound hypotension and a variety of bizarre E.C.G. changes, including A-V block, multifocal extrasystoles, and ventricular tachycardia, together with broadening and distortion of the QRS complex. Corresponding E.C.G. patterns in poisoned children have been described and discussed by Giles (1963) and by Braun *et al.* (1965).

The two unconscious patients in the present series (Cases 26 and 31) developed neither severe hypotension nor any arrhythmia, and electrocardiograms were not recorded ; however, we may have overlooked prolonged ventricular tachycardia (Jacobziner and Raybin, 1963). E.C.G. monitoring should therefore form part of the management of all severely affected patients.

The findings by Cairncross and Gershon (1962) that these severe manifestations of toxicity can be precipitated by an increase in cardiac work load has three important practical implications: (1) That complete control of convulsions is imperative and that sedation and bed rest should be continued for as long as E.C.G. changes are liable to be detected—that is, for three days or more. (2) That the use of hypertensive agents is to be deprecated. In the presence of a healthy vasculature and parasympathetic blockade, vital organs are unlikely to suffer ischaemic damage until the systolic blood pressure has been well below 80 mm. Hg for several hours (Bloch *et al.*, 1966). (3) That large intravenous infusions are dangerous ; this constitutes a further argument against forced diuresis in the treatment of this type of poisoning.

The parasympathomimetic agent pyridostigmine has been shown, both experimentally and clinically, to be of some value in preventing or reversing the cardiotoxic actions of the tricyclic antidepressants (Rasmussen, 1965, 1966), and the same author recommends the use of propranolol for the control of arrhythmias arising in this situation. Cardiac failure in association with ventricular tachycardia was partially relieved by procainamide in Case 15 (Jacobziner and Raybin, 1963), but an analogue, xylocaine, has been shown to have less depressant effect on the myocardium (Harrison *et al.*, 1963) and has become the drug of choice for the suppression of arrhythmias after myocardial infarction (Lown *et al.*, 1967). The adult dose is 25–50 mg. intravenously, followed by continuous intravenous infusion of 1–2 mg./min.

Attempts to stimulate the myocardium with calcium (Somuncuoglu, 1960) or lanatoside C (Garrison and Moffitt, 1962) have not met with demonstrable success, and in the presence of A-V block with ventricular extrasystoles the use of cardiac glycosides would be contraindicated.

The possible influence of the phenothiazines which were alleged to have been taken in combination with imipramine or amitriptyline in Cases 26 and 31 cannot be assessed at present, but the value of phenothiazines in the management of tricyclic antidepressant poisoning warrants further study. There is a complex pharmacological relation between the two classes of compound (Klerman and Cole, 1965), and they have some toxic actions in common (Gordon and McCandless, 1959 ; Irwin and Burlew, 1959). Chlorpromazine has, however, been used in the management of psychotic behaviour occurring as a side-effect of imipramine therapy in adults (Boardman and Fullerton, 1959) and in the treatment of the syndrome associated with the simultaneous ingestion of imipramine and a monoamine oxidase inhibitor (Saunders, 1965). It proved effective in controlling the agitated behaviour in our patient (Case 31), but no superiority has been demonstrated over the paraldehyde or chloral used by others.

Conclusions

A scheme for the management of the severe case of imipramine or amitriptyline poisoning, as derived from the above discussion, may be summarized as follows:

(1) Gastric aspiration and lavage should be carried out as soon as the patient reaches hospital.

(2) Intramuscular paraldehyde should be given as soon as convulsive movements appear.

(3) The patient should be carefully observed, with E.C.G. monitoring, and nursed in surroundings as free as possible from extraneous stimuli.

(4) Oxygen and/or assisted ventilation should be provided as indicated by the clinical state and by blood-gas analysis.

(5) A slow intravenous drip of an isotonic solution, such as dextrose with half-strength Ringer's lactate, should be established.

(6) If arrhythmias or circulatory failure supervene, xylocaine and pyridostigmine (but not hypertensive agents) should be added to the drip.

(7) In the event of cardiac arrest there should be no hesitation in applying full resuscitative measures (see Case 16 of Fruthaler and Snyder, 1963).

(8) While consciousness is being regained, sedation in the form of chlorpromazine, chloral, or paraldehyde should be given.

(9) Relaxation of strict bed rest should be allowed only after a minimum of three days, provided that the E.C.G. is then normal.

Summary

Attention is drawn to the increasing incidence of poisoning due to the ingestion of imipramine and amitriptyline by young children. Twelve non-fatal cases are reported, and compared with 21 others in the literature, including five deaths.

Mildly affected children exhibit drowsiness—sometimes alternating with excitement—tachycardia, ataxia, and sometimes dilated pupils. In more severe cases convulsions and coma rapidly supervene. Arrhythmias and circulatory failure may occur and can prove fatal. These severe symptoms always appear when the ingested dose exceeds 20 mg./kg., though much smaller doses may suffice.

Early gastric lavage is indicated. Peritoneal or extracorporeal dialysis is ineffective and forced diuresis is contraindicated. Treatment of the severe case is symptomatic. Paraldehyde is preferred to barbiturates in controlling convulsions. Xylocaine and pyridostigmine may have a place in the management of arrhythmias, but hypertensive agents are contraindicated.

Careful observation should include E.C.G. monitoring. Sedation is required during recovery, and bed rest should continue for a minimum of three days.

We are grateful for the valuable help in the preparation of this paper given by Professor J. O. Forfar, Dr. Henry Matthew, and Professor L. G. Whitby. Drs. J. W. Farquhar, D. M. Douglas, W. M. McCrae, and H. Simpson offered constructive criticism and encouragement, and gave permission to report cases admitted under their care. Thanks are also due to the staff of the Poisoning Treatment Centre, Edinburgh Royal Infirmary, who co-operated in the management of Case 31; to Mrs. C. Palmer, Ministry of Health Statistician, who provided the data for the Chart; and to Dr. W. Kondradt for assistance with translations.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Typhoid Immunization after Measles

Q.—*Is it safe to give T.A.B. or T.A.B.T. vaccine to a child aged 5 within five weeks of the onset of an attack of measles?*

A.—Clinical and immunological responses to T.A.B.T. vaccination are not affected by a previous attack of measles, provided the period between the onset of the rash and the time of vaccination is more than four weeks and the patient has clinically recovered from the measles and any complications.

Though immune responses, such as the tuberculin reaction, are temporarily depressed by measles the effect rarely persists for more than four weeks. The marked leucopenia of the prodromal period is even more transient. The leucocyte count returns to normal soon after the rash appears. There is no reason, therefore, why T.A.B.T. should not be administered in the case in question.

Ranges of Forced Expiratory Volume

Q.—*What is the normal range for the forced expiratory volume in one second (F.E.V$_1$.) in adults and in children?*

A.—The normal forced expired volume in adults depends upon the sex, age, and size of the subject. One of the largest series of normal values was measured in 468 normal men by Kory *et al.*,[1] and they produced a nomogram from which the *average* value for the F.E.V.$_1$ can be measured in relation to a subject's age and size. They found that the best measurement of size was height, which was more closely related to the F.E.V.$_1$ than weight or surface area.

In adults the F.E.V.$_1$ decreases by about 0.03 litres per year of age, so that the average F.E.V.$_1$ for a man of 170 cm. tall and aged 20 is about 4.1 litres, whereas in a man of the same height age 60 it is only 2.9 litres. Of course, from such regression relationships of F.E.V.$_1$ in relation to age and size only the average expected value is obtained, but there is a scatter of values about this average depending on the standard deviation. The latter for the adult F.E.V.$_1$ is about 0.5 litre in men and 0.4 litre in women. That means that for a given age and height 95% of normal subjects will have an F.E.V.$_1$ within a range of about half a litre plus or minus of the expected average for that height and age. For example, 95% of women aged 40 and 160 cm. tall would be expected to have an F.E.V.$_1$ of between 2 litres and 3 litres, since the expected average for that age and height in women is 2.5 litres.

There is a good discussion of all this problem of normal values in Cotes's book on lung function.[2] It contains regression graphs for men and for women from which the average F.E.V.$_1$ for a given age and height can be seen and to which average the scatter, expressed as plus and minus standard deviation, can be added.

In children the same principles for obtaining the normal range apply, though here the F.E.V.$_1$ increases with age, since age is itself directly related to an increase in size. Age is a relatively poor standard for comparison of children, since children of the same age often differ in size. It is usual to get the average normal value for boys and for girls only for their height, and to add and subtract the standard deviation from this average to get the normal range. Strang,[3] Cherniack,[4] Murray *et al.*,[5] and Bjure[6] have all reported normal values for children, and Cotes's book again gives graphs for boys and for girls from which normal values can be read. Four graphs (for men, women, boys, and girls) should be used to read the range of normal values for both sexes and all ages. Of course, different graphs would be needed for different races, such as negro subjects as opposed to Caucasian stock.

Predicting Height

Q.—*At what age is a child supposed to be half his eventual adult height, and how accurate is the prediction?*

A.—Children who are growing at the average rate reach half their eventual adult height at 2.25 years if a boy or at 1.6 years if a girl. The normal limits are wide, however, and half adult height could be reached anywhere between 1.5 to 3 years in boys and 1.25 to 2.25 years in girls. The prediction of adult height from length at these early ages is not good, the correlation being of the order 0.7.

Exercise and Blood Calcium

Q.—*Does exercise have any effect on blood calcium and the triglyceride levels?*

A.—Most commonly employed methods measure the total plasma calcium. This level is influenced by meals, so that only fasting levels are valid if comparisons are to be made. Furthermore, it has been shown there is both a day-to-day and a seasonal variation in a given individual which may amount to 0.6–1.4 mg./100 ml.[1] The second factor to be considered is that calcium exists in three states in the blood—as free ions, bound to protein, and a small amount complexed to organic acids. It is possible for variations to occur within these fractions without the change being reflected in the total calcium level.

The plasma calcium accounts for a small proportion of the calcium in the body and a dynamic equilibrium exists between the various compartments, notably the blood and the main reservoir in the skeleton, so that any change in plasma calcium in response to exercise is likely to be short-lived. Isotope studies using Ca-47 have demonstrated that exercise produces an increased calcium turnover.[2] Excretion of calcium is reduced during moderate exercise,[3] and brief but severe exercise produces a temporary rise in total blood calcium.[4]

This was also shown by Radcliff *et al.*,[5] who studied the effect of venous stasis and venous stasis accompanied by exercise of the forearm muscles, and were able to demonstrate statistically that both the exercise and stasis could produce an increase in the plasma calcium level. Clearly, all specimens examined for calcium levels should be drawn from fasting patients, preferably without the application of a venous tourniquet and clenching of the fist to promote filling of the veins.

The plasma triglyceride level is also markedly affected by food intake, and any change in response to exercise must be considered in relation to the fasting level. After a meal containing fat the plasma triglyceride level rises, reaching a maximum after about four hours and reverting to fasting levels in about six hours. Exercise—for example, a route march—results in a four-hour level little different from the fasting level, and the six-hour level may be lower than the fasting level.[6 7] If short-term exercise is carried out in fasting subjects there is a fall to below the initial triglyceride level.[8] In a more prolonged study in middle-aged men Holloszy *et al.*[9] showed that six months of physical conditioning produced a significant reduction in mean fasting triglyceride levels.

Notes and Comments

Pain in the Back.—Dr. J. MARKS (Cardiff) writes: Your expert ("Any Questions?" 22 July, p. 223) neglects the fact that we spend a third of our lives in bed. My wife's disabling backache of some years' duration vanished at once on our changing an ordinary bed for an "orthopaedic" model sold commercially. A much milder backache which I had disappeared similarly. The discarded bed seemed to be in quite reasonable condition.

OUR EXPERT replies: It is true that a large proportion of patients with backache are made worse by sleeping on an unsuitable type of bed. The orthopaedic model, however, is expensive, and much the same effect can be obtained by sleeping on fracture boards placed between the mattress and the base. I am, nevertheless, grateful to Dr. Marks for reminding me of this important point.

Book Reviews

Environment and Ophthalmology

Culture, Race, Climate, and Eye Disease. By Ida Mann, C.B.E., M.A.Oxon, D.Sc., M.B., B.S.Lond., F.R.C.S.Eng., F.R.A.C.S. (Pp. 580+xi; illustrated. $21.00.) Springfield, Illinois: Charles C. Thomas. 1966.

In our thoughtful moments we all recognize that half the human population is subsisting on a starvation diet, but it rarely crosses our minds that probably a similar proportion is diseased and we prefer not to think of the morbidity which this entails. In *Culture, Race, Climate and Eye Disease* data on this subject have been collected by several methods: from official hospital records, from certificates of blind registers, from the ophthalmic scientific literature, and from the relatively few planned surveys which comprise the only method likely to give dependable results. The collected facts provoke the author to state in her early chapter on General Considerations, "It will be seen soon how little we really know."

Nevertheless, new ground has been broken in this volume by inspecting ophthalmology from a vantage point which is astronautical in its width of horizon. Essentially a primer because our knowledge is so patchy and incomplete, it nevertheless lays bare a challenge of enormous complexity and size to medical men and modern methods. Some of the questions which may find an answer from such studies are the relationship of heredity and environment in disease, the effects of diet, climate, and culture on disease, and the correlation of ophthalmic disease with microbiological inhabitants of the same area.

This study opens with chapters on the more remote and primitive cultures. The first 100 pages are concerned with islands mainly in the Southern Hemisphere. From these the author passes to the Arctic, to Africa, to Mongolia, to the Indian Peninsula, and approaches the Western World via the Middle East. 160 pages are given over to the complex Western culture, which is rapidly threatening to engulf all others. The final chapter discusses world distribution of certain eye diseases. There is a workable index, and references to the literature are given at the end of each chapter.

There are so many facts in this volume on the incidence of ocular syndromes that it is quite impossible to condense them or even understand their significance at times. As an example it is pointed out that blindness from glaucoma measured in percentage of blind persons ranges from 52 in Iceland to 0.8 in Australia. What does this mean? Nevertheless, the overall message is that blindness from infection and malnutrition is characteristic of the under-privileged section of the human race whereas the dangers of our own progressively richer culture are essentially industrial, genetic, iatrogenic, and geriatric.

STEPHEN MILLER.

Neurology Today

Modern Trends in Neurology, 4. Edited by Denis Williams, C.B.E., M.D., D.Sc., F.R.C.P. (Pp. 293+ix; illustrated. 75s.) London: Butterworth. 1967.

This is the fourth successive volume in the series and the third to appear under the editorship of Dr. Denis Williams. Its predecessors have kept neurologists up to date in scientific and clinical research relevant to their study of human nervous disease, and they have also provided a bird's-eye view of the current neurological landscape for less specialized physicians. Their continuing usefulness as sources of reference has been ensured by the inclusion of authoritative reviews on headache, arachnoiditis, intracranial aneurysm, internal carotid artery occlusion, and polyneuropathy, to mention only a few.

Judged by such standards the reviewer must confess that his first reaction to the present book is one of slight disappointment, and even some suspicion that it might be cited in support of the view occasionally expressed by the neurologist's colleagues in internal medicine that his subject makes an unimpressive showing in the matter of clinical research. Such an assessment of the book would be hardly fair. Dr. Williams is surely right to refresh each new edition with contributions from younger and less established workers in the field, and the comprehensive coverage accorded to some current clinical problems in previous editions, precludes their further presentation without risking considerable repetition.

Nevertheless some sense of regret remains that there is little here to make neurology exciting to the general physician and a good deal that is of limited interest even to the clinical neurologist. The key to this situation lies in the editor's preface, which stresses the contribution of both clinical and experimental neurology to our study of "the integrative function of the brain," the elucidation of normal behaviour, and the clarification of the boundaries between physical structure and psychological activity. This may indeed "anticipate the needs of sophisticated, busy neurologists." On the other hand, it expresses a traditional British view of clinical neurology as a handmaiden of neurophysiology, according to which the patient's illness is interesting mainly for the light it throws on normal function. This is in striking contrast to the modern American neurologist's preoccupation with the epidemiology, aetiology, experimental pathology, and even (save the mark!) the treatment of nervous diseases. It is significant that twelve of Dr. Williams's sixteen contributors work in the metropolis, nearly all in the shadow of Queen Square. More closely integrated with general medicine, British neurology outside London leans towards the more clinical and pragmatic American viewpoint.

For the unsophisticated clinician the book gets off to a heavy start with twenty pages on the ventral tier thalamic nuclei by M. B. Carpenter and thirty-three of scrupulous anatomical observations on lesions produced by stereotactic surgery (Marion Smith), followed by an account of the motor neurone surface as the basis of an interesting theory on the nature of spinal shock (L. S. Illis). In the third chapter A. M. Halliday elaborates his previous studies of myoclonus in an exhaustive review which will be a useful source of reference. This is followed by Malcolm Piercy on the neurological basis of intellectual function, D. A. Pond on the brain-damaged child, Macdonald Critchley on developmental dyslexia, and W. I. McDonald on experimental neuropathy. Dr. J. B. Cook discusses the prognosis of spinal injury, and his chapter is followed by three on various aspects of cerebrovascular disease, one on angiography and a brief account of H. E. Webb's views on the significance of immune reactions in viral infections. Marcia Wilkinson discusses the neurological implications of all the unpleasant things that can happen to the cervical spine, and the editor closes with some observations on the management of myasthenia gravis, which is a reflective rather than a practical guide to procedure—though he comes down heavily in favour of early thymectomy. The chapters on the pathology and surgical treatment of cerebrovascular disease add little to what has already been written: the surgical author regrets the absence of controlled evaluation of carotid surgery but states that it is "very effective" in the treatment of intermittent ischaemic attacks. Wilkinson's chapter on the cervical spine is a useful catalogue, and the section on angiography is also in the nature of a textbook account.

Judgement on the relative merits of the various contributions is bound to depend on personal interests, and the reviewer's pleasure in Cook's account of the socio-economic implications of the aftermath of spinal injuries and Spalding's excellent description of the neglected field of circulatory disorders due to neurological disease reflects his relief that there are still neurologists who can lift their eyes from the neurone. "*Modern Trends 4*" will be bought, read, and discussed by all who are interested in neurology. General physicians who can overcome their feelings of unworthiness that they are not more excited by its first seventy pages will also find many pearls concealed in its text.

HENRY MILLER.

Emphysema Described

The Pathology of Emphysema. By Lynne Reid, F.R.A.C.P., M.R.C.P., F.C.Path. (Pp. 372+ix; illustrated. 70s.) London: Lloyd-Luke. 1967.

It is easy to think one knows about emphysema until one starts thinking and reading about it. The inquirer then finds himself groping in semidarkness through a confusion of terminology, conflicting pathology, confident but contradictory clinical observations, and sparse but exotic experimental work, the whole experience having the qualities of a Danteesque nightmare, from which one hopes to wake and find after all it just isn't true. Indeed, a lot of it probably isn't. Dante, when making his well-publicized descent, took the precaution of engaging as his guide the sage Virgil, who conducted him with remarkable sang-froid around the infernal circles.

The explorer of the no less formidable abyss of emphysema would be well advised to retain Dr. Lynne Reid as dragoman. She pursues a calm and systematic course, coolly recounting the relevant, making reasonable inferences when they are justified, and giving ignorance its due when evidence is insufficient. Much of the work is her own, or that of her immediate colleagues, but she refers to that of many others, and there is an excellent bibliography.

It is right that a study of emphysema, which has to be defined in pathological terms, should start from pathology, but there is very much more than pathology in this book. Dr. Reid has much to say on radiology, which, with Dr. George Simon, she has correlated with pathological findings. There is also a good deal on the clinical and functional manifestations of emphysema. Many of the points are illustrated with relevant case histories. The classification of emphysema, however provisional, seems to make sense and to be a reasonable basis on which to found further work. There is a good section on the pathology of chronic bronchitis, in the study of which the author has been a pioneer, and a useful appendix on the normal anatomy of the lung. The diagrams and illustrations are excellent.

No doubt experts in the field will find one thing or another in this book with which to disagree, but most of us must indeed be grateful for an intelligent and intelligible approach to a difficult and confusing subject.

JOHN CROFTON.

Care of the Cleft Palate

Treatment of Patients with Clefts of Lip, Alveolus and Palate. Symposium, Hamburg, 1964. Edited by Karl Schuchardt. (Pp. 237; illustrated. 84 DM.) Stuttgart: Georg Thieme. 1966.

This volume reports verbatim the second symposium held in Hamburg on the treatment of patients with clefts of lip, alveolus, and palate. Fourteen of those taking part were also contributors to the first symposium ten years earlier. Topics for discussion were introduced by invited speakers, after which three-minute contributions were made by any delegate who wished; in this way it was hoped to avoid set papers which would have been of little value to an expert audience well versed in the principles of the subject matter and to promote instead well-informed discussion of controversial issues. The topics chosen were broadly grouped into three categories: the primary treatment of patients with clefts, the disorders of growth and function after primary operations and their treatment, and documentation.

In the first category topics included the incidence and aetiology of clefts, their morphology, early orthodontic care, and logopedic problems as well as modern surgical procedures. The second category was mainly concerned with secondary corrective procedures and with the disorders of growth which made these necessary. Broadly planned the topics included dental, orthodontic, and E.N.T. aspects, besides considering the surgical contribution to the alleviation of speech defects. The third category produced two valuable discussions on documentation in which R. B. Stark (New York) gave an introductory survey of an embryological basis for a new classification of cleft lip and palate and G. Pfeifer (Hamburg) described the system of documentation worked out for use in Schuchardt's clinic. Contributions by P. Fogh-Andersen (Denmark), B. Vilar-Sancho (Spain), J. Converse (New York), and T. R. Broadbent (Salt Lake City) indicated the need and desire for the establishment of an internationally acceptable classification born of uniform documentation.

This is not a beginner's book. It is a study in depth of the most difficult problems of this most difficult subject; and it succeeds. It is for the surgeon who is intimately concerned with these problems and responsible for the day-to-day care of these deformed children. The reader can enjoy the considered opinions of acknowledged experts both in invited comment and in free discussion, testing his own beliefs and practice against the verbatim reports of their views. In this way it brings him into the discussions as he reads, and offers him the opportunity to modify his own ideas or the justification to continue as before as his judgement dictates. Professor Schuchardt is to be congratulated on convening this symposium, on the scope of its work, and on the method of presentation of the outcome. It is to be hoped that in due time a third similar symposium will be held and that it will be reported in a volume as well set out and illustrated as the present one by Thieme Verlag.

DAVID MATTHEWS.

Biological Control at Many Levels

Regulation and Control in Living Systems. Edited by H. Kalmus. (Pp. 468+viii; illustrated. 90s.) London: John Wiley. 1967.

Dr. Kalmus is reader in biology at University College, London, and his book consists of 16 sections, three of which he has written himself, and one in collaboration, while the other 12 sections are by eleven other authors, a number of them being colleagues at University College. Apart from an introduction and a conclusion the sections are grouped under the three main heads of "Cells and Individuals," "Development and Genetics," and "Groups and Populations."

Under the first head are five papers. "Molecular regulation in the cell," by the botanist D. Lewis, gives a condensed account of how enzyme synthesis may be controlled by special genes called operators and regulators. It was work in this field for which Jacob and Monod were recently awarded a Nobel prize. This account of it, however, is difficult for beginners. "Physiological control systems," by Kalmus and B. R. Wilkins, describes some applications of engineering ideas to human eye movements, to temperature regulation, and to invertebrate eye function and orientation. D. B. Fry reviews "the control of speech and voice," G. Kalmus in "circadian regulation and related responses" gives a very brief account of some diurnal rhythms, and K. Brown-Grant gives a very detailed review of experiments demonstrating the hypothalamic-anterior pituitary control of thyroid, adrenal cortex, and ovary in "regulation and control in the endocrine system."

Under the second head we find an essay by J. S. Wilkie describing eighteenth century work on regeneration in polyps and worms, and brief and all too short accounts of "regulation of plant growth," by P. R. Bell, and "regulation in animal development," bv D. R. Newth. Under the third there is an interesting account by J. B. Free of the self-regulation of the honey bee population in a hive, and the indication by V. C. Wynne-Edwards that animal populations practice birth-limitation, and that very primitive man did likewise, so that modern man is somewhat out of step in his conflict over birth control.

All life being the antithesis of chaos must involve many kinds of control, and the present reviewer is not convinced that the bringing together inside one book of scattered examples of control at all levels of complexity from all over biology is intellectually useful. It certainly makes for cramped pedestrian writing and difficult reading. The value of the book lies in the usefulness of one or two of its review articles.

J. L. CRAMMER.

Forms and Patterns of Childhood Illness

The Psychiatric Disorders of Childhood. By Charles R. Shaw, M.D. (Pp. 442+ix. $11.50.) New York: Appleton-Century Crofts. 1966.

So few books are published on child psychiatry that the appearance of a new one is likely to arouse keen interest, which in this case may be blunted for many by a glance at the table of contents, which does not appear to follow any recognizable system. After opening chapters on heredity, experience, case finding, and diagnosis, the real substance of the book is in the third section on "specific disorders." It is completed by brief sections on treatment and perspective. Thus it is clear that the book is primarily concerned with forms and patterns of illness and not with the living child.

Although much of the writing is illuminated with warmth and humour, Dr. Shaw appears to mistake order and method for science in his very cut-and-dried presentation. For example, he sets out 139 itemized reasons for referral among 500 consecutive patients at the Hawthorn Center, and names 36 functions of the ego. But to give a list of 28 types of "behavior functions affected by heredity," without differentiation between the evidence taken from observations of caged animals, free domesticated animals, wild animals, and human beings, is to act very unscientifically indeed.

The children are presented in static poses to illustrate some "specific disorder" or other. There is no movement, no development, no family life. Claiming that history is unimportant in child psychiatry—"the clinical examination is everything"—Dr. Shaw is consistent when he is prepared to diagnose brain damage in the absence of any history of damaging circumstances; but inconsistent in not also requiring the presence of clinical signs of damage. All that he requires is that the child's behaviour should resemble that of children "in proven cases of brain damage such as post-encephalitic . . . or known severe cerebral anoxia at birth." But he does not indicate how the damage can be "proved" when the children first have to live long enough after their disaster to serve as behaviour models before their brains can become available for histological examination. Where change and development are unrecognized, diagnosis, in Dr. Shaw's own words, may become a "vexing" problem, for whenever the child comes up "with a new symptom-complex . . . he has to be picked out of one pigeon-hole and put into another."

Where there is no individual or family history, social and cultural problems may appear no less confusing. The first essential is to do full justice to the fact that children are growing and developing and live in families. Before this book can contribute something new to thought and practice in the modern field of child psychiatry such factors have to be taken into account.

KENNETH SODDY.

Glasgow History

The Victoria Infirmary of Glasgow. History of a Voluntary Hospital. 1890–1948. By Ian Murray. (Pp. 89; illustrated.) Obtainable from the Board of Management for Glasgow Victoria Hospitals, 24 St. Vincent Place, Glasgow C.1. 1967.

A just tribute is paid to the Glasgow Southern Medical Society by the author of this attractive little book, for he states that "it was due to their continued advocacy that the Victoria Infirmary in large measure owes its inception." The infirmary was opened in 1890 with 84 beds, but it was soon extended, and the stages of its growth are carefully and chronologically recorded in the first ten pages of the book. In 1948 it was handed over to State control as a fine, well-equipped, well-staffed hospital of 500 beds together with Philipshill Auxiliary Hospital.

The main part of the book consists of brief biographies of the chief physicians, surgeons, and specialists who served the infirmary during the period of its existence as a voluntary hospital. Many of the earlier members of the staff had experience as general practitioners before they became consultants. Among the early surgeons Maylard is perhaps the best known as a pioneer in abdominal surgery. Of the specialists at least two gained international reputations—Brown Kelly in laryngology and Albert Alexander Gray in otology. The first pathologist was Thomas Kirkpatrick Monro, who later became regius professor in the university; the author mentions his *Manual of Medicine* but omits to tell of his later well-known compilation *The Physician as a Man of Letters.* The best-known physician attached to the infirmary was that brilliant writer O. H. Mavor, better known as James Bridie. He was a good physician but as a dramatist he won world renown. Dame Louise McIlroy was a Glasgow graduate and was at one time on the staff of the Victoria Infirmary. The present gynaecologist, Sir Hector MacLennan, as the author says, "has brought much lustre to the Victoria."

The last five pages are devoted to an account of the various architects who helped to plan and construct the infirmary—a well-deserved but often overlooked tribute.

ZACHARY COPE.

Introduction to the Operating Theatre

Demonstrations of Operative Surgery. 3rd edition. By Hamilton Bailey, F.R.C.S., F.A.C.S., F.R.S.E. Revised by A. R. Isaac, F.R.C.S.(Ed.). (Pp. 431 + xii; illustrated. 50s.) Edinburgh and London: E. & S. Livingstone. 1967.

This edition, like the previous ones, is described as "a manual for general practitioners, medical students, and nurses," and it retains the original format. The first section is concerned with general principles of operating theatre technique, the second with endoscopic procedures, and the remaining ten sections with accounts of most of the common surgical operations. These last are arranged regionally and are written in the form of demonstrations in the first person. They are all short and clear, and are accompanied by helpful lucid illustrations.

Operative surgery, however, cannot be considered in isolation, and further editions would benefit enormously from a discussion of the role of anaesthesia, blood-transfusion, preoperative and post-operative care, and of the complications which might be encountered during and after operation. Admittedly some of these aspects are mentioned in passing, but in general they are not given the prominence which they deserve.

However, within the strict terms of the title, this book could hardly be bettered for those to whom it is directed, and nurses undergoing theatre training will find it particularly helpful.

R. B. WELBOURN.

Books Received

Review is not precluded by notice here of books recently received.

Doctor Sahib. By Stephen Kerry. (Pp. 204. 30s.) London: Cassell. 1967.

Laboratory Outline in Physiology. 2nd edition. By the Staff of the Department of Physiology, University of Toronto. Edited by R. E. Haist and L. W. Organ. (Pp. 81+iii; illustrated. 48s.) Toronto: University Press. London: Oxford University Press. 1967.

The Development of Modern Surgery. By Frederick F. Cartwright. (Pp. 323+x; illustrated. 50s.) London: Arthur Barker. 1967.

New Aspects of the Mental Health Services. Edited by Hugh Freeman and James Farndale. (Pp. 776+xvi. £9 9s.) Oxford: Pergamon. 1967.

Lecture Notes on Endocrinology. By Ronald F. Fletcher, B.Sc., M.D., M.R.C.P. (Pp. 277 +viii. 25s.) Oxford and Edinburgh: Blackwell. 1967.

Bacteriology and Immunity for Nurses. 2nd edition. By Ronald Hare, M.D. (Pp. 201+ix; illustrated. 21s.) London: Longmans. 1967.

Gray's Anatomy. Descriptive and Applied. 34th edition. Edited by D. V. Davies, D.Sc. (Lond.), M.A.(Cantab.), M.B., B.S., F.R.C.S. With the assistance of R. E. Coupland, M.D., Ph.D., F.R.S.E. (Pp. 1669+xv; illustrated. £8.) London: Longmans. 1967.

Great Ideas in the History of Surgery. 2nd edition. By Leo M. Zimmerman, M.D., and Ilza Veith, M.A., Ph.D. (Pp. 587+xii; illustrated. 24s.) London: Constable. 1967.

Diabetes Mellitus. Lehrbuch für Ärzte und Studierende. 2nd edition. By Professor Konrad Seige. (Pp. 245+xii. £3 0s. 9d.) Leipzig: Georg Thieme. 1967.

Proceedings of the Second International Congress on Hormonal Steroids. Edited by L. Martini, F. Fraschini, and M. Motta. (Pp. 1172+xv; illustrated. $57.00.) Amsterdam: Excerpta Medica. 1967.

The Year Book of Neurology, Psychiatry and Neurosurgery. 1966–1967. Edited by Roland P. MacKay, M.D., Sam Bernard Wortis, M.D., and Oscar Sugar, M.D. (Pp. 757; illustrated. 83s.) London: Lloyd-Luke. 1967.

Hormone Chemistry. By W. R. Butt. (Pp. 397 +xiv; illustrated. 75s.) London: D. Van Nostrand. 1967.

Animal Toxins. Collection of papers presented at the First International Symposium on Animal Toxins, New Jersey, 1966. Edited by Findlay E. Russell and Paul R. Saunders. (Pp. 428+ xiii; illustrated. £6.) Oxford: Pergamon. 1967.

Strontium Metabolism. Proceedings of the International Symposium held at Chapelcross, Glasgow, and Strontian, 1966. Edited by J. M. A. Lenihan, J. F. Loutit, and J. H. Martin. (Pp. 354+xiii. 84s.) London: Academic Press. 1967.

Methods and Achievements in Experimental Pathology. Vol. 2. Investigative Techniques. Edited by E. Bajusz and G. Jasmin. (Pp. 289; illustrated. sFr./DM. 58.) Basel and New York: S. Karger. 1967.

Diagnostica Pneumoradiografica in Medicina Interna. By Luigi Lacrois. (Pp. 350; illustrated. No price given.) Rome: Il Pensiero Scientifico. 1967.

Mental Disorder. A Problem with many Facets. By Man Mohan Singh, M.B., B.S., D.P.M. (Pp. 378. 7s. 6d.) London: Pan. 1967.

Psychiatric Disorders in Obstetrics. By A. A. Baker, M.D., D.P.M. (Pp. 140+viii. 27s. 6d.) Oxford: Blackwell. 1967.

GENERAL PRACTICE OBSERVED

Hythe Medical Centre—an Appraisal

G. H. WARRICK, M.A., M.R.C.S., L.R.C.P., D.C.H.

Brit. med. J., 1967, **3**, 672–674

The Hythe Medical Centre has been working for two years—too short a time for full assessment. I feel, however, that interest in the health centre concept has developed so rapidly that objective criticism can now be useful. The opinions expressed are my own, and I hope will lead to further discussion and perhaps a truer picture. The centre was described when it was opened (*B.M.J.*, 3 July 1965, p. 42), and not long afterwards your Special Correspondent (*B.M.J.*, 11 December 1965, p. 1425) recorded comparative attitudes to the centre and our group practice centre at Blackfield.

The Centre

The centre is attached to Hythe General Practitioner Hospital and provides accommodation for three general-practitioner firms, visiting consultants, and local authority services, including a school dental unit, child psychiatric clinics, and speech and audiometry clinics. It contains a new casualty department, a small *x*-ray unit, and facilities for electrocardiography. The pathology room is available mainly for consultative advice, for specimen collection, and as a depot. The name "medical" rather than "health" centre seemed to describe its function more aptly. The hospital has 22 beds—11 maternity and 11 general—and a physiotherapy department. The reception and office are managed by an administrative officer appointed by both county and hospital boards, with a staff of 11 part-time secretaries. The records include those of the N.H.S., the consultant sessions, and the school medical service. Health visitors and district nurse-midwives are attached to practices and work from the centre.

History.—Hythe lies between Southampton Water and the New Forest. Southampton is 11 miles (18 km.) away by road. Between Hythe and Fawley is an industrial belt which includes the Fawley Refinery. In 1959 the three larger practices in the area were beginning to think of increasing their surgery accommodation because of the steady rise in the population. As a group of doctors we knew each other well. We shared a general practitioner hospital and had founded our own medical society. Some of us had already sought special help from the county medical officer, who had allowed health visitors to assist in running our baby clinics. It was he who approached us to seek advice in siting a proposed welfare clinic, and then entered with enthusiasm into our common interest in the possibility of a comprehensive health centre. Although Hythe Hospital was already listed for closure under the hospital plan, we insisted that the centre must, so far as was possible, be combined with it. A desire for more accommodation and better diagnostic facilities had broadened to include an ambitious scheme to lower the barriers within the tripartite health service in our part of the country.

Planning.—This seemed incredibly difficult. Our main difficulties were that agreement in policy lagged behind design. Considerable time could have been saved if we had decided on the basic design of surgery accommodation and the various sections of the building before the building itself was discussed. Planning of centres will now be easier with access to existing centre designs. The most depressing delay occurred because ministerial study of the plans took more than 10 months. A great improvement should now accrue from the formation of a ministerial department with special knowledge of health centres. Expert criticism should help to remove faults in design and may even speed building. In retrospect I regret our too ready acceptance of parts of the building which did not then seem to be our direct concern. In fact, every aspect of work in a health centre is in some way important. I am sure, too, that where costs have to be reduced the plans should be discussed by the doctors themselves. We could have suggested several items that might have been omitted without detriment. The most notable feature of planning was a committee representative of all three branches of the Health Service in the area.

The Building

The building is attractive, bright, and pleasant to work in. The three main wings meet at the reception and office area and the main entrance. In criticizing lay-out and shape, I think points may be made in favour of a design based on a "circulation diagram," avoiding the necessity of everyone tending to meet at one point. The single-storey building saves building costs but increases the spread and the distance to be walked. The tile floor covering is attractive and wears well, but I would now be in favour of carpet over concrete, with a lessening of noise.

Each general-practitioner suite comprises two consulting-rooms with two intervening examination rooms. This arrangement is ideal for antenatal and baby clinics, for a midwife or health visitor can then use the second consulting-room. I miss a secretary/nurse close at hand, and a great improvement would be a small practice office for her, with space for the health visitor. Our real failure was in the design of the office and reception area. Doctors' secretaries need more privacy and space, and problems arise from the grouping of several telephones in a constricted area. Our open counter with adjacent office space is about to be screened and secretaries will be given more room. If there is a central office the practice suites must be next door. Two of ours are much too far away.

Adjacent to the centre is an ambulance station, which ensures speedy transfer of patients from the maternity unit or casualty department to the major Southampton hospitals.

Administration

One of the major advantages to the patient is the availability of his or her own doctor, consultant, health visitor, and district nurse-midwife, and diagnostic services under one roof. Appointments can usually be arranged with great ease at the same counter. The charge that in health centres a patient is less able to see his own doctor is unfounded. Where real difficulty does arise is in the impossibility of several secretaries, often interchanging duties, knowing one's practice and the idiosyncrasies of the patients as did the doctor's wife or practice secretary. So far as possible one secretary for each practice copes with the visiting-list, repeat prescriptions, and practice business during the morning surgery. One secretary arranges appointments for the three practices. In my view the real problem in health centres is the maintenance of family practice in which the doctor is not too "distant" and the secretary is able to allay the anxieties of the patient. I think a nursing or paramedical training will become increasingly necessary for a secretary. After all, it is she who decides on priorities.

General Practice in a Health Centre

How has our work altered ? Can we give our patients a a better service ? I find the environment good for medicine and the ease of consultation with specialist and colleagues an advantage. The greatest advance, perhaps, is in the growing use of the medical team as a unit in general practice—the family doctor, the health visitor, and the district nurse-midwife. I am now more conscious of being a personal doctor than before. Can you really be one with an N.H.S. list of two to three thousand and no help ? Close proximity to the hospital ensures that the doctor is quickly available to the labour ward or casualty department. Antenatal clinics can cover both hospital and district cases with help from both hospital midwife and district nurse-midwife. The health visitor broadens the work of the practice and shares its burden.

The casualty department and practice treatment room will soon be combined, with a resultant saving of nursing time. District midwives can deliver short-stay cases in hospital. Perhaps midwives will one day go out from the hospital and work in the district. A mental welfare officer works from the centre. His help to our patients and to ourselves is of great value. A common room is available to everyone. Here one may meet the children's officer, the probation officer, or the parish priest.

In the Hythe area each school has a general-practitioner medical officer. We usually work with a health visitor from another practice, and thus between us know two-thirds of the children seen.

An Integrated Medical Service

At Blackfield, 5 miles (8 km.) away, we have a group practice centre to look after the other half of two of the practices. An automatic exchange links the two centres. A group practice centre certainly has the advantage of speed in building. Here, too, changes in structure or policy can be rapidly implemented. I think that a health centre is the answer when integration with a hospital or with local health authority services on a large scale is envisaged, but otherwise private enterprise is certainly less cumbersome. Twelve doctors work from the two centres, and provide the area with an integrated medical service. A house committee meets at Hythe ; it consists of our hospital matron, administrative officers of hospital and centre, and doctors from each practice. Hythe Medical Society continues to fulfil a most important role in linking us together and enabling us to meet our consultant colleagues professionally and socially. The three practices, however, retain their complete identity and do not share a rota system except for casualty work.

The Future

A health centre should be an ideal place for planning health education, and we have started some schemes here. This centre should also make a good base for general practice research, but so far no plan has been adopted. It is possible that we would need expert advice, with secretarial and financial assistance. Time spent on consultation increases steadily, and it is thought that time could be saved by bringing some patients to us by special transport arrangements.

Plans are advanced towards setting up a high-frequency radio link between the centre, doctors, and midwives. The suggestion has been made that doctors working from health centres should be salaried. We have no wish for this, and seek to retain our independence. Finally I am sure that this centre must remain an experimental venture, and also that there must be pooling of knowledge on the design and administration of health centres to aid their future development in this country.

Summary

An attempt is made at an objective criticism of the Medical Centre at Hythe. Some suggestions are included regarding possible planning for future health centres, particularly in relation to reception and office arrangements.

The main advantages of health centre practice are the availability to the patient of his or her own doctor and easy access to consultant advice and diagnostic aid.

The centre encourages the concept of a medical team in general practice. Together with a neighbouring group practice centre the area now has an integrated medical service.

STUDENT HEALTH

Hospital Admissions among Students during a Three-year Period

GRAHAM GRANT,* M.SC., M.B., B.S.

Brit. med. J., 1967, 3, 674–676

A recent leading article in the *British Medical Journal* (1967) discussed the special arrangements needed for the management of psychological problems among university students. It also contained the following comment about their physical health: "He [the student of 30 years ago] suffered from influenza, the occasional inflamed appendix, and athletic injuries . . . The incidence of these physical maladies has altered little." In other words, students are to be regarded as a comparatively healthy group exempt from serious illness or disability. How true is this?

Reference has been made to the prevalence of chronic illness and to the special problems of handicapped students who, as a result of a more enlightened educational approach, are reaching university in increasing numbers (Grant, 1960). In a report of the Expert Committee on University Health Services (W.H.O., 1966) the suggestion is made that, in fact, a "wide range of acute and chronic medical and surgical disorders is seen." A brief study of the reasons for admission to hospital among students attending the University of Newcastle upon Tyne during a three-year period (September 1963 to August 1966) certainly lends support to this view.

Sources and Nature of Information

Shortly after its inception in 1963 arrangements were made for the university health service to be notified of the admission of students to the main teaching hospital in the area. Initial information about admission to other hospitals was obtained from medical certificates accounting for absence from studies, copies of which were sent to the health service by the university administration. Information came also from tutors and the wardens of halls of residence who were concerned about the implications of absence through illness or injury, which in some instances had occasioned admission to hospital either in the student's home town or elsewhere.

Clinical information was obtained in a number of ways. As the period covered by the inquiry progressed, an increasing number of students were registered with the university health service general practice, and reports about hospital admissions among them were received in the usual way, but in a number of instances follow-up inquiries had to be initiated as a result of information received from one or other of the sources mentioned in the foregoing paragraph. Sufficient diagnostic information was invariably available for purposes of simple classification.

It is inevitable that a survey of this kind should be incomplete. In particular, information about admissions during university vacations is likely to have been defective, though knowledge of admissions during term will have been more reliable.

Results and Discussion

Student numbers (postgraduates included) varied somewhat from year to year during the three years under review, with a mean annual figure of 4,610. Approximately one-quarter of the students were women.

During the three years 213 men were admitted to hospital on 229 occasions for the investigation or treatment of 215 different conditions, and 120 women were admitted on 129 occasions for 124 conditions. Altogether, therefore, 333 students were admitted on 358 occasions for 339 conditions. There was little annual variation in the proportions admitted, and a reasonable interpretation of the findings would be to say that annual admission rates were between 2 and 3% of the total population at risk, with, as might be expected, a somewhat higher proportion of women admitted than men. Analysis of causes of admission into broad categories according to the *International Classification of Diseases* is given in the Table. In some instances diagnostic descriptions have been adapted or modified for the sake of brevity. Because of the small numbers in some of the subgroups, the findings in the sexes have been combined. Much of the Table is self-explanatory, but five of the items call for special comment.

Group V

Mental, psychoneurotic, and personality disorders predominated as a cause of admission. (In fact, 36 men were admitted on 47 occasions and 24 women on 28.) The difficulties of psychiatric diagnosis among late adolescents and young adults are well known, and though the neat classification given in the Table may not be entirely accurate it reflects the spectrum of psychological disorders among students and underlines the importance of adequate facilities for dealing with them. The majority of students are, of course, living away from home, sometimes in flats or bed-sitters, or in other circumstances where it is unreasonable to expect to find anyone prepared to exercise the care and responsibility these cases demand ; and admission to hospital may be essential to the preservation of group morale even when a disturbed student is living in a university residence. Social reasons which would not necessarily be operative in a family setting may therefore contribute towards an inflation of admission rates considerably above the level expected among members of a similar age group in the community at large.

---

* Senior Medical Officer, University of Newcastle upon Tyne Health Service.

It is of interest that, of the 60 students admitted, 24 (40%) were women. Admission for mental breakdown also occurred disproportionately among foreign students. Approximately 8% of the total student population were from overseas. None of the women students admitted with mental illness were expatriates, but seven of the men—that is, one-fifth of the men admitted—came from abroad. The findings as regards women and foreign students in respect of mental illness are in agreement with those reported elsewhere (Kidd, 1965 ; Maclay, 1967).

Three Years' Hospital Admissions. Analysis by "Final" Diagnosis According to International Classification of Disease (Sexes Combined). (Numbers of Cases in Parentheses)*

	Admissions	
	No.	%
(I) *Infectious and Parasitic Diseases* Respiratory tuberculosis (2), tuberculosis (other) (4), hydatid (1), paratyphoid (1), filariasis (2), glandular fever, infectious hepatitis, other virus diseases (10) ..	22	6·2

(IX) *Diseases of Digestive System* Disorders of occlusion, eruptions, etc., of teeth (chiefly admission for extractions of 3rd molars under endotracheal anaesthesia)	36	10·1
Duodenal ulcer (2), appendicectomy (23), hernia (2), ulcerative colitis (3), refashioning of ileostomy (1), fibrocystic disease (1), observation appendicitis (5), other (5)	43	12·0
(X) *Diseases of Genitourinary System* Infections of kidney (2), hydrocele (3), other (3), phimosis (1), gynaecomastia (2), disorders of menstruation (4), twisted ovarian cyst (1), ovarian cystectomy (1)	18	5·0
(XI) *Deliveries and Complications of Pregnancy, Childbirth, and the Puerperium* Normal delivery (19), caesarean section (1), abortion (6), therapeutic termination (6) .. .. .. (Total: 32—i.e., 24·8% of all female admissions)	32	8·9
(XII) *Diseases of Skin and Cellular Tissue* Erythema nodosum (1), drug eruption (2), infections of skin and subcutaneous tissue (5)	8	2·2
(XIII) *Diseases of Bones and Organs of Movement* Loose body in knee, meniscectomy (7), ruptured intervertebral disc (1), other symptoms referable to back (1)	9	2·5
(XVII) *Accidents, Poisoning, Violence* Accidents causing death (6), found dead (2), injuries involving fractures or dislocations (19), multiple lacerations, contusions, concussion (19) other injuries (5)	51	14·3
Total admissions	358	100·0

* The number of admissions may be greater than the sum of the numbers in parentheses because some individuals were admitted on more than one occasion.

Deaths (12)		
	Accidental	6
	Found dead	2
	Malignant hypertension ..	1
	Neoplasms	3

Group I

Overseas students also contributed disproportionately to the admissions for infectious and parasitic diseases. Apart from conditions obviously of tropical origin—for example, filariasis—five of the six cases of tuberculosis occurred in foreign students, who altogether accounted for one-third of the admissions in this group. These findings demonstrate the need for special screening of overseas students either before or as soon as possible after their arrival.

Group XI

It will be noted that 32 women were admitted for "deliveries and complications of pregnancy and the puerperium," comprising a quarter of the total admissions among women students. The findings relate only to cases admitted to hospital and known to the university health service. It may well be that during the early formative period of the work of the service, while students were developing confidence in it, some preferred to take such problems elsewhere. Moreover, a number of pregnancies which occurred during the last year of the inquiry had not gone to term by the end of it and are consequently excluded. Pregnancy rates based on the figures in the Table would therefore be misleadingly low. Working in a well-established university health department, Finlay (1965, 1966), who has made a special study of the problem, estimates that between 2 and 3% of unmarried women students become pregnant each year. Not all the pregnancies enumerated in the Table occurred in unmarried students, but accumulating experience at Newcastle supports Finlay's observations.

There is no doubt that problems of personal relationships, marriage, and child-bearing are occurring with increasing frequency in university health practice. It is important to get them into perspective, however. Hitchens and James (1965), using data derived from the Registrar General for England and Wales relating to 1961, gives rates for extramaritally conceived maternities—that is, illegitimate maternities plus those occurring within nine months of marriage—per 1,000 unmarried women at risk. For the age groups 15–19 and 20–24 these were 27.3 and 63.3 per 1,000 respectively. Since an unknown proportion of pregnancies—variously estimated at between 12 and 20% (Macnaughton, 1966)—end in abortion, the rates for extramaritally conceived maternities must be a good deal lower than the pregnancy rates. Assuming an annual pregnancy rate among unmarried women students (age range, say, 18–25) to be currently of the order of 3%, there is little evidence to support the view that they suffer this particular consequence of sexual misbehaviour or misadventure disproportionately by comparison with other women of similar age.

Group XVII

Serious injury among students, often resulting in prolonged absence, and, especially in cases of head injury, sometimes presenting the most difficult problems of rehabilitation, was most commonly caused by road traffic accidents. Among less serious injuries (multiple lacerations, contusions, concussion, etc.) sometimes requiring only overnight admission, again the road traffic accident and—a sinister social commentary—the unprovoked assault figured more prominently than athletic injuries.

Deaths

Lastly, there is the "melancholy list of deaths" (Paget, 1869) given at the foot of the Table. This refers only to deaths occurring while *in statu pupillari,* and the contribution of trauma—that is, road traffic accidents—to mortality in this age group is underlined. In some instances the student was dead on arrival at hospital, and these ought strictly, perhaps, to have been excluded from the total of hospital admissions, but the picture would have been incomplete without them. Two students were "found dead" in circumstances which aroused suspicion of suicide—a surprisingly small number bearing in mind the size of the population at risk over a three-year period and experience at other universities (Rook, 1959).

Conclusion

The report of the W.H.O. Expert Committee and a report of the Royal College of Physicians (1966) both recommended that university health services should provide their own accommodation, preferably centralized, for the treatment of certain categories of sickness among students. This is not the place for a description of how such accommodation might best be organized or of the undoubted advantages it confers. It will suffice to say that in common with a number of universities this service is now being developed at Newcastle upon Tyne, and some cases which might formerly have been admitted to hospital will in future be admitted to it.

This note should not, of course, be thought to reflect the scope and volume of clinical and preventive work in a comprehensive university health department the facilities of which are extended, in one form or another, to all members of the university community. It is clearly incomplete even as a prevalence study of morbidity among students. But if it does nothing else, at least it should dispose of the notion, still evidently held in some quarters, that—psychological disorders apart—a description of illness among students is adequately covered by "influenza, the occasional inflamed appendix, and athletic injuries" and that students are seldom really ill at all.

This work, part of a larger study into the implications of morbidity among university students, was supported in part by a grant from the Nuffield Provincial Hospitals Trust.

NEW APPLIANCES

New Alarm for Treatment of Nocturnal Enuresis

Mr. H. J. TERRY, Department of Medical Electronics, St. Bartholomew's Hospital, London E.C.1, writes: Alarms for the treatment of nocturnal enuresis, as described by Gillison and Skinner (1958), are in widespread use. The first aim in designing a new one was to minimize the risk of "buzzer ulcers," which were investigated by Borrie and Fenton (1966). The opportunity was taken to make the unit not only safer but also more reliable and more easily used and maintained than types employing relays, bells, or buzzers. Since high-quality silicon transistors now cost only two or three shillings, the cost of construction is only slightly increased.

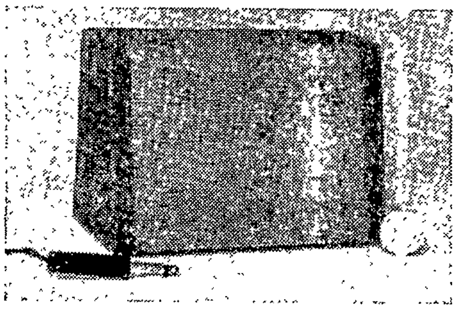

FIG. 1.—Enuresis alarm unit and a two-shilling piece.

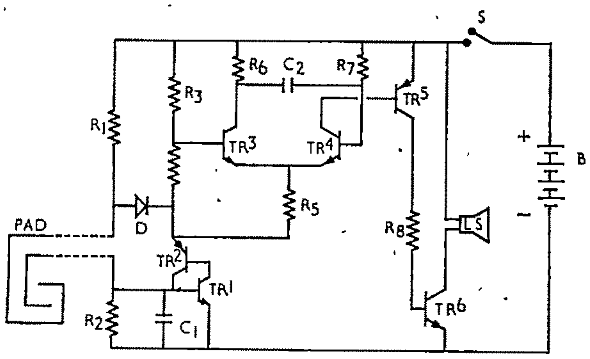

FIG. 2.—Enuresis alarm circuit. Components list: R 1, 5,600 ohms. R 2, 1,000 ohms. R 3 and 4, 4,700 ohms. R 5 and 6, 820 ohms. R 7, 470,000 ohms. R 8, 220 ohms. C 1 and 2, 0.01 microfarad. TR 1, 3, and 4, 2N 3710 (Texas Instruments). TR 2 and 5, 2N 3702 (Texas Instruments). TR 6, 2N 3706 (Texas Instruments). D, 1S940 (Texas Instruments). L S, loudspeaker 25–35 ohms. Battery, 4 cells, U 12/D 14.

Operation of the alarm has been made as simple as possible. As in earlier systems, a pad with two isolated electrodes is placed under the bottom sheet in the patient's bed and connected by a length of flex to a jack plug. Pushing the jack plug into its socket closes the switch, and the alarm is then ready for use. When the alarm is triggered by urine reaching the pad the loudspeaker wakes the patient with a steady note. This is switched off by simply unplugging the pad, and the alarm is again ready for use as soon as a dry pad is plugged in. The unit is powered by four pen-torch cells, which are sufficient for several months' use.

In answer to a letter in the *British Medical Journal* (Terry, 1966) 16 inquiries were received from doctors interested in trying out the new alarm. Nineteen alarms were built and sent out, with forms on which the user was asked to record each day whether the bed had been wet in the night and if the alarm had functioned correctly. Records of 40 months' use of alarms have so far been received, and as a result of the favourable reports by doctors and patients the alarm is being produced commercially.*

The unit is shown in Fig. 1 and the circuit diagram in Fig. 2. For those interested in electronics, TR 1 and TR 2 act as a switch, which responds to a current through the pad of about 400 microamps. With TR 1 and 2 conducting, TR 3 and 4 act as an emitter-coupled astable multivibrator. TR 5 and 6 merely amplify the square wave so produced, and drive the loudspeaker. Two safety features are included. R 1 ensures that, even if a fault occurs elsewhere in the circuit, the current through the pad cannot exceed 1 milliamp. The diode, D, provides the further safeguard that once the alarm has been triggered the potential across the pad cannot exceed 1 volt. To avoid false alarms when switching on it may be necessary to add a capacitor, similar to C 1 and C 2, between the base and emitter of TR 2.

I wish to acknowledge the help given by members of the Department of Medical Electronics in making the alarms, and by the medical officers, general practitioners, and patients in testing them. I am also grateful to the Endowment Fund of the hospital for financial support.

Medicine in Burma

SIR,—Professor A. W. Woodruff's most informative article "Medicine in Burma Today" (26 August, p. 551) will interest many who feel profoundly towards that lovable land and people. May I, however, with the double interest of a founder professor of Rangoon University and of a former medical adviser to the British Government on Colombo Plan affairs, point out that by electing to leave the Commonwealth Burma did not deprive herself of British and Commonwealth aid. Both the Colombo Plan and the British Council gave generous help to Burma over the years and we still receive Burma nationals freely for specialist training and provide technological aid on the spot.

The London School of Hygiene and Tropical Medicine has played a most prominent part in shaping Burmese thought in medical administration, but tribute should be paid to the Edinburgh colleges—especially the Royal College of Physicians—for training the new generation of teachers. The outstanding claim for British influence rests on the Royal College of Obstetricians and Gynaecologists, whose members—male and female—are playing such an important part in modern Burma.

With the historical example of Judson, the pioneer American missionary who opened up Burma, and the great record of America in fostering education in Burma (we in British University College faced American Judson College on the university campus in the 'twenties) it is a matter for profound regret that the Burmese have felt it advisable to refuse further American aid, but with Thailand and Viet Nam round the corner their attitude is understandable. Professor Woodruff's own contribution to Burmo-Britannic concord is outstanding and his sympathetic study is therefore very welcome.—I am, etc.,

Ewell, Surrey. GEORGE R. MCROBERT.

SIR,—It was very heartening to read the paper by Professor A. W. Woodruff "Medicine in Burma Today" (26 August, p. 551). His paper gives an excellent survey of the medical services in that country. Naturally one would not expect from a professor of tropical medicine (any more than from a professor of radiology) an account that did not have an emphasis towards his main interests—in this case towards tropical medicine. This letter is written in no spirit of criticism, but merely to emphasize some of the aspects not fully covered in Professor Woodruff's paper.

The medical services in Burma have indeed undergone a revolution, and this has happened in particular since the present revolutionary council took over the government of the country. All medical practice is concentrated on hospitals and health centres. There is no longer general practice as we know it in Britain. In the larger towns, where under previous regimes there was general (and private) practice for the privileged few who could afford to pay for it, this has been discouraged or eliminated, and all medical practice is now concentrated within the Government medical service.

The medical school based on Rangoon General Hospital has always had a high reputation and produced doctors of high calibre. This now applies also to the new well-equipped medical schools at Mingaladon and Mandalay. However, as doctors trained in hospital where there are reasonable ancillary facilities were continuing to work subsequently in other hospitals, whether those hospitals were divisional or township hospitals, the demand for the continuance of ancillary facilities was considerable, though at the time the ability to satisfy these demands was minimal or non-existent. Thus an Institute of Paramedical Sciences was set up at Rangoon General Hospital to train laboratory technicians, radiographers, physiotherapists, and pharmacists. This Institute has been in action for nearly three years and is now producing a flow of trained technicians in these disciplines. I have been concerned with this concept since its beginning and visit it regularly year by year. In modern medical practice medicine cannot be practised satisfactorily without ancillary aids, and it is important in the context of Burma to realize that this essential "substructure" of medicine is now being established.

With the "substructure" of medicine established, and with the excellent medical schools, described by Professor Woodruff, already in existence, it only remained to plan the "superstructure" of the specialist fields. This has now started, and Professor Woodruff described one of these—that in tropical medicine. However, in addition, apart from the major fields of surgery, medicine, and obstetrics and gynaecology, the specialist fields of child health, pathology, anaesthetics, orthopaedic surgery, and radiology are now being developed. Already there are diploma courses for a Burmese diploma in anaesthetics and another in clinical pathology. These, together with the present course in tropical medicine, and the possibility of developing further postgraduate courses in other fields such as radiology, make it seem possible that Rangoon may well grow into a postgraduate centre of considerable significance in South-east Asia.

All these advances have taken place in Burma during the past five years, in a country which already had a first-class medical school whose medical degrees have recently been given full recognition by our own General Medical Council. The substructure and superstructure are now being built, just as they were in Britain many years after the undergraduate teaching hospitals were established. There is a considerable fund of good will in Burma towards Great Britain besides the traditional medical links that have existed for many years. It is to be hoped that the United Kingdom will continue to provide training facilities and hospitality for those Burmese doctors and medical technicians who come here for further experience, and in addition will continue to second medical and paramedical personnel at all levels to Burma to help them with the exciting developments that are now taking place.—I am, etc.,

J. H. MIDDLEMISS.

Department of Radiodiagnosis,
University of Bristol.

SIR,—Professor A. W. Woodruff's article "Medicine in Burma Today" (26 August, p. 551) refers to the recognition by the General Medical Council of Burmese medical degrees but does not tell the whole story.

It would seem that in 1964 the Burmese Government refused to permit foreign graduates of the Burmese School to practise in Burma unless they had 14 years' previous Government service. This has had the result that non-Burmese nationals qualifying in Rangoon are unable to obtain full registration in Britain because they are no longer permitted to practise in Burma. This political decision has meant that, while Burmese nationals qualifying in Rangoon may obtain full registration here, non-Burmese nationals who passed precisely the same examination are no longer so entitled.

Two points arise: firstly, should not the relevant section of the 1956 Medical Act 18(1)(c), which entitles persons holding certain foreign degrees to obtain full registration in Britain, be so amended as to avoid anomaly of a person's entitlement to registration here being dependent upon what appear to be purely political considerations? Secondly, should Burmese nationals be granted rights in Britain while their Government shows such discrimination?—I am, etc.,

HERBERT CONSTABLE,
Secretary,
Medical Protection Society.

London W.1.

Penicillin Encephalopathy

SIR,—Your leading article on penicillin encephalopathy (12 August, p. 384), while drawing attention to the hazards of intravenous penicillin therapy, makes little attempt to indicate how these hazards may be avoided or to define the indications for using penicillin G in this way.

In July my colleagues from Boston and I described eight patients treated with high doses of intravenous penicillin G in whom there was evidence of neurotoxicity.[1] These patients were compared with seven others treated similarly in whom toxicity was not observed. All patients were assessed as regards renal function, electrolyte imbalance, plasma, and cerebrospinal fluid penicillin levels. Major differences were noted between the two groups in respect of amount of penicillin administered and penicillin C.S.F. concentration; the group with fits tended to have lower serum sodium values than those without fits. No patient with a lumbar C.S.F. penicillin concentration less than 10 units/ml. had a fit; clearly, whatever the state of renal function or the blood/C.S.F. barrier it is unwise to exceed this concentration of penicillin in the C.S.F. The other complications of infusion of large doses of penicillin G are fluid and electrolyte imbalance, which can be avoided or corrected, and haemolytic anaemia, which is quite rare.

Intravenous penicillin G in doses of 20 to 100 million units per 24 hours is not only a useful form of therapy for septicaemia due to *Clostridium welchii* and selected Gram-negative species but may be the only effective therapy in certain patients with endocarditis. For those who may wish to administer these doses it is important that indiscriminate use is avoided and that the limitation of dosage based on C.S.F. penicillin levels be understood.—I am, etc.,

HILLAS SMITH.

Royal Free Hospital,
Infectious Diseases Department,
London N.10.

Treatment of Staphylococcal Endocarditis

SIR,—Your leading article (4 March, p. 515) concluded that the best treatment for staphylococcal endocarditis is a combination of a penicillin or cephalosporin with an aminoglycoside (streptomycin or kanamycin). The patient with poor renal function presents a special problem in that the dosage of the aminoglycoside must be carefully monitored by assays of blood levels in order to avoid toxic side-effects.

A chance finding led to the realization that both cephaloridine and cloxacillin in serum can be neutralized by an excess of *Bacillus cereus* penicillinase. A patient with "sterile" endocarditis being treated with penicillin G and streptomycin was having serum streptomycin levels assayed daily. The penicillin was destroyed with commercial penicillinase (Neutrapen) and the streptomycin assayed by a microbial method. The levels remained surprisingly constant even after cephaloridine had been added to the regimen unbeknown to the laboratory.

As a result of this I set up a chessboard titration to compare the action of the penicillinase against varying concentrations of methicillin, cloxacillin, cephaloridine and penicillin G. The antibiotics were dissolved in phenol-red broth, and concentrations of penicillinase varying from 2 up to 400 units were added. Destruction of the antibiotic was indicated by the growth of a small inoculum of the Oxford staphylococcus after 18 hours' incubation. The results are shown in the Table.

Weight of Antibiotic	Penicillin G	Cephaloridine	Cloxacillin	Methicillin
500 μg.	16	160	>400	>400
50 „	16	80	400	>400
5 „	<2	16	80	400

Penicillinase units needed to neutralize the antibiotic.

An average blood level of antibiotic would be 5 μg./ml., and it can be seen that 400 units of penicillinase destroyed this amount of all four antibiotics. Similar results were obtained with a different make of penicillinase (Distillers), and also after the addition of 25% human serum to the medium.

These results agree with biochemical studies on penicillinases in general and bacterial work on the staphylococcal enzyme.[1 2] Whether there is a single beta-lactamase or separate penicillinase and cephalosporinase enzymes is still in doubt[3]; certainly the enzymes produced by different species of bacteria vary in their relative activities against penicillins and cephalosporins.

I conclude that the readily available *Bacillus cereus* penicillinase is a definite help to the medical microbiologists for the neutralization of cephaloridine, cloxacillin, and possibly methicillin in the blood of a patient when either blood levels of other antibiotics or blood cultures are required.—I am, etc.,

Mortality of the Ambulance Ride

SIR,—On Christmas Eve, 1966, my father, who was not a doctor, died of a coronary in the Postgraduate Hospital at Hammersmith. On the way to the hospital he asked me to try to alter the design of ambulances for cardiac cases, in as much that with the head-first position the abdominal contents rode up towards the chest every time the driver applied the brakes. This caused my father a considerable increase in his pain.

On reflection surely it would be better if all patients were carried in ambulances with their feet nearest to the driver, as even in the unconscious case the legs and body would protect the head from injury in an accident, whereas in the present system the head is smashed against the partition behind the driver. Facing the engine is often preferable in railway trains, and the only reason I can assume for our present policy of the patient lying facing the rear door of the ambulance is the reluctance of the authorities to agree to stretchers being carried feet first, possibly because the old expression "They carried him out feet first" has the connotation of dying or death.—I am, etc.,

JOHN R. GLOVER.

Department of Social and
Occupational Medicine,
Welsh National School
of Medicine,
Cardiff.

SIR,—I missed Dr. D. Lamont's letter (6 May, p. 374), but the letter of Dr. C. H. Cullen and colleagues (12 August, p. 438) deserves a comment from a totally different angle. In the first world war it was widely known and recognized that many cases of serious gunshot wounds often had better recovery prospects when they had been left for longish periods exactly where they were wounded.

I can speak from personal experience. I was crashed when flying in France as a passenger and became conscious before my squadron ambulance arrived. I was able to recognize that I was extensively paralysed. Being at that time aware of the benefit of no movement at all for a longish period, I forbade my anxious orderly to en-stretcher me, and made him cover me with rugs until an M.O. from the officers' hospital in St. Omer came and personally supervised my transport two hours after the crash.

The Army consultant, General Dawson (later Lord Dawson of Penn), attributed my ultimate recovery largely to this period of immobility.

All this is now 51 years ago. Years and years passed, and I had the misfortune to witness a motor-cyclist near Barnet involved in a bad accident. I remember vividly the difficulty I had in preventing him being immediately lifted on to one of those two-wheeled horrors, then in common use by the St. John Ambulance. He made a good recovery, thereby sparing the driver of the car involved in the accident standing a possible trial for manslaughter. The report of the casualty surgeon at the hospital to Lord Trenchard, then Commissioner of Police, produced a personal letter from Trenchard asserting the view that a longish period of immobilization had been of material help in this cyclist's recovery.

I wonder if the value of immobility at the site of injury with a resuscitation tent has ever been explored, before even a short motor journey, however good the springing.—I am, etc.,

C. B. HEALD.

Chipping Campden,
Glos.

SIR,—The plea of Mr. C. H. Cullen and his colleagues for improvements in ambulance suspension (12 August, p. 438) deserves strong support.

A few weeks ago I had occasion to accompany a patient who had suffered a subarachnoid haemorrhage a day or two previously to a neurosurgical centre. The journey covered 25 miles of good road which I know well, but I was appalled at the rough ride experienced, which was reminiscent of travel in a farm-cart.

I was greatly apprehensive that the shaking the patient received might restart the haemorrhage, and I felt the back of a saloon car would have been a far safer place in which to carry her.

New ambulances are, I understand, to have much better suspension of a pneumatic type, but could not something be done to improve the existing ambulances, which will be with us for many years to come?—I am, etc.,

J. HORTON.

Problems of Accident and Emergency Services

SIR,—It was refreshing to read Dr. K. C. Easton's comments on road accidents at the B.M.A. Bristol Meeting (22 July, p. 230). For some years a few general practitioners have been emphasizing the value of a doctor on the site of an incident, if this can be attained without delay.[1]

Unfortunately there has developed a widespread misunderstanding of what is possible in primary treatment by the general practitioner on the site, and how they can help to reduce the possible 20% preventable deaths in transit.

In my area the present policy of the accident service has produced a Gilbertian situation. The police, who are the organizers of the medical care at an incident, have been advised by the Medical Officer of Health that it is undesirable to inform a local general practitioner of an accident near him if the patient is alive, as this would cause delay in treatment by the accident hospital unit. However, the local doctor may well be informed if the patient is dead—to certify death.

Factual evidence of saving life, when a doctor has attended on site at an accident by chance, has made no impression on this policy. In this practice three, possibly four, lives have been saved during the past few years in the small percentage of accidents attended. Admittedly there are pros and cons on the subject. But any local accident medical organization that has as its policy "call the local doctor if the patient is dead, but don't call him if he's alive" must be suspect.

Some of us hope that a wind of change may start blowing through the opinions of the higher echelons of the accident service organizers as a result of Dr. Easton's talk.—I am, etc.,

ROBERT HOWARD.

Mercury Perchloride in Surgery of Bowel Cancer

SIR,—Mayo Robson[1] drew attention to the problem of seedling implantation in radical cancer surgery. To avoid this implantation during mastectomy Sampson Handley[2] advised flushing the wound with 1:2000 perchloride of mercury solution. Miles[3] used a stronger 1:500 solution of perchloride of mercury after radical resection of the rectum, for its antiseptic rather than its anticancer action.

The use of the solution as an anticancer agent in colon and rectal surgery was popularized by several workers[4-6] and has been found efficacious. Keynes[6] stated that there was no evidence of mercury poisoning in any of the cases he had studied, but he gave no details of blood or urinary mercury levels. Royle[7] described a case of alleged mercury intoxication following the use of 200 ml. of 1:500 perchloride solution during the excision of a tumour of the renal pelvis, and this report prompted study of the question.

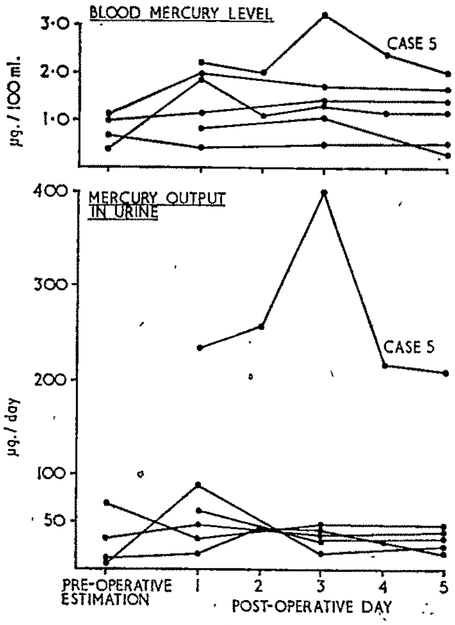
Six patients with rectal adenocarcinoma were studied (see Table). The urine output of mercury and the blood level of mercury were measured pre- and post-operatively. The technique of rectal restorative surgery employed was essentially that described by Goligher *et al.*[4] In this about 1 litre of 1:500 mercury perchloride solution is used to wash out the rectal stump, while a further 300 ml. is used to mop the lumen of the proximal colon when it is divided, and also to wash the edge of the mesentery and the exposed perirectal tissues in which malignant cells released by lymphatic division and direct tumour extension may lie.

When radical resection was performed the cut edge of the mesentery, the perirectal and perineal tissues, and the divided proximal end of the colon were mopped with the solution, which was dried up before the abdomen was closed. Again the surgeon was allowed only 300 ml. of 1:500 mercury perchloride for all these needs.

Details of Patients Studied

No.	Sex	Age	Clinical Details	Maximum Urinary Mercury Concentration (μg./litre)
1	F	54	Carcinoma rectosigmoid Restorative resection	58
2	M	74	Carcinoma rectal ampulla Abdominoperineal resection	26
3	M	50	Adenoma sigmoid colon Local resection	24
4	M	66	Carcinoma rectal ampulla Abdominoperineal resection	24
5	M	60	Carcinoma rectosigmoid Solitary metastases dome of bladder Restorative resection with partial cystectomy and wide pelvic fat clearance	232
6	F	66	Carcinoma rectal ampulla Abdominoperineal resection	38

Details of the six patients studied are shown in the Table, and the results are shown graphically (see Fig.). No patient showed clinical evidence of mercury intoxication, and six of the cases showed an inappreciable uptake of mercury into the blood. Case No. 5, however, showed higher urine values than the others, which were possibly due to the mercury put inside the bladder and "contaminating" the urine, to the more extensive pelvic dissection and the difficulty of drying the mercury out adequately, or to a selective uptake of mercury occurring in the bladder. Because the blood levels were only slightly raised we suspect that the first of these possibilities was responsible. Thus mercury fixes exposed cells such as those in the bladder, and these would be shed over the ensuing days, leading to the higher urine levels demonstrated in this case. Though the evidence for increased mercury uptake by bladder epithelium is slight, three previous cases of mercury intoxication involving bladder surgery are reported by Page and Wilson,[8] though they used mercury oxycyanide.



Lane[9] states that the normal urine mercury content is up to 80 μg./l., and that quantities in excess of 100 μg./l. are abnormal. Moreover, he further points out that symptoms of mercurialism develop when the level exceeds 300 μg./l. The highest level found in the series was 232 μg./l. in Case No. 5 within 24 hours of operation. No patient, however, showed any signs of mercurialism, and it is therefore concluded that mercuric perchloride is a safe anticancer agent when it used, as described above, in large bowel surgery.

I am grateful to Mr. R. W. Nevin and Mr. H. E. Lockhart Mummery for permission to study patients under their care and to Dr. R. B. McSwiney for biochemical facilities.

—I am, etc.,

Elusive Popliteal Pulse

SIR,—You have done an important service to your readers (5 August, p. 326) by raising a matter of such practical importance, and, while the consensus of opinion is that there are several best ways of palpating for the popliteal pulse (19 August, p. 495), no mention is made of a much more exact technique for obtaining the information which the popliteal pulse is meant to supply. I refer to oscillometry.

Like sphygmomanometry, oscillometry greatly enhances the accuracy of what at best can be regarded as only a subjective impression.—I am, etc.,

Nalidixic Acid and Intracranial Hypertension

SIR,—In a letter (5 August, p. 370) Dr. O. D. Fisher reports a case of raised intracranial pressure in a child during treatment with nalidixic acid. He states, "In the present case the dosage of nalidixic acid prescribed for the infant was twice the recommended one of 100 mg. per kg. body weight per day, and this was used in the second course to see if the condition could be reproduced."

The dose of 60 mg./kg. body weight is the one recommended by us and is the one which appears regularly in our literature. On this basis you will see that the doses used in the case reported by Dr. Fisher were in fact over three times the recommended dose of 60 mg./kg. body weight.

Nalidixic acid is widely used in hospital and general practice for the treatment of urinary tract infections, both in children and in adults, and it would indeed be unfortunate if doses other than those recommended by the manufacturers were quoted in medical journals and used unsuspectingly by doctors. —I am, etc.,

Achondroplasia and Leukaemia

SIR,—We were interested in the Clinicopathological Conference (3 December 1966, p. 1371) describing immunologic deficiency and aplastic anaemia in an infant with achondroplasia. Dr. V. A. Fulginiti and associates (22 April, p. 242) and Dr. J. A. Davis (8 July, p. 110) have written of similar cases, prompting us to report the case history of an achondroplastic child who developed leukaemia, and to speculate on a relation between this complication and the other disorders observed with achondroplasia.

On 3 January 1965 a boy aged 5 years was admitted to the Children's Cancer Research Foundation in Boston with the abrupt onset of a superior vena caval syndrome. A classical picture of achondroplasia had been evident since birth, in the absence of a family history of dwarfism or congenital defects, and during infancy the patient had respiratory difficulty, which was attributed to a deformed thoracic cage. In addition to achondroplastic dwarfism examination showed facial oedema, venous distension in the neck and chest wall, and hepatomegaly. The white-cell count was normal with 40% lymphocytes. *X*-rays revealed an anterior mediastinal mass and bony changes consistent with achondroplasia. A presumptive diagnosis was made of lymphosarcoma. Because of rapidly increasing dyspnoea, the patient was treated with *x*-ray therapy and adrenal steroids, followed by dramatic improvement. Intravenous vincristine, 0.6 mg. weekly, was given in an attempt to prevent conversion of lymphosarcoma to leukaemia.

On 4 April the patient complained of headache and vomiting. The white count was 13,000 with 4% blast cells, and bone-marrow aspiration showed acute lymphocytic leukaemia. Lumbar puncture revealed meningeal involvement with leukaemia, which was treated with intrathecal methotrexate. One month later the white count was 19,400 with 44% blast cells, and the platelet count was 7,000. Despite treatment with methotrexate, cytoxan, and adrenal steroids the subsequent course was progressively downhill, and the patient died on 12 September 1965. Necropsy revealed the osseous abnormalities of congenital achondroplasia, extensive leukaemic infiltration of organs, a haemorrhagic diathesis due to thrombocytopenia, and terminal bacteraemia.

To our knowledge there have been no previous reports of achondroplasia and leukaemia occurring in the same person, so that this case may represent a combination of chance events. Its signifiance is enhanced, however, by the concurrence of achondroplasia with immunologic deficiency and marrow aplasia, conditions which independently appear to carry an excess risk of leukaemia or lymphoma.[1] Thus leukaemia may be an added manifestation of an immuno-haematologic defect occurring in certain patients with achondroplasia.

If this association is not due to chance one may wonder about the role of chromosomal abnormalities which have been observed occasionally in achondroplasia.[2] It is of interest that the congenital disorders which are at high risk of leukaemia (Bloom's syndrome, Fanconi's syndrome, and mongolism) have chromosomal abnormalities in association with skeletal defects or dwarfism.[1] However, the recent description of osteogenesis imperfecta and childhood leukaemia in two siblings[3] suggests that the relation of leukaemia to heritable disorders of the skeletal system need not be mediated by cytogenetic defects. As noted by Dr. Davis, the disorders associated with achondroplasia seem to extend the list of syndromes which bring together genetically determined diseases of the bone and bone marrow.—We are, etc.,

Smallpox Revaccination

SIR,—In our county the health authorities are advocating routine revaccination against smallpox of children between 8 and 9 years of age.

My partners and I think this is against modern teaching. Besides carrying a slight risk to the child, so many people require yet a further revaccination in their late teens owing to foreign travel. This appears to make procedure at 9 years superfluous.

We have written to our medical officer of health saying that we are advising parents against this routine procedure. He has replied suggesting that we alone are upsetting the records for the county. Are we really being "square" or are there other general-practitioner nonconformists ?—I am, etc.,

Horsham, Sussex. E. PERKINS.

Changed Character of Osteomyelitis

SIR,—I had not intended to enter into correspondence on your leading article (29 July, p. 255), as I have previously discussed most of the controversial points.[1-4] However, I have been unable to resist the temptation to make a few comments.

My own experience supports the opinion of Mr. J. H. Bulmer (19 August, p. 497) that cloxacillin is the antibiotic of choice before the sensitivity of the organism is known, and in this context Mr. J. H. Green's paper (13 May, p. 414) was a most helpful contribution. I am quite convinced that bacteriostatic antibiotics such as the tetracyclines have no part to play in the management of staphylococcal osteomyelitis, and there is no better one than cloxacillin for use against the penicillinase-producing staphylococcus. A further disadvantage of the tetracyclines is their relative inability to diffuse into dead bone.[5] I have shown quite conclusively that penicillin and methicillin diffuse readily through thick-walled abscesses and remain in the infected tissue long after the blood level has fallen to zero.

I regret that I cannot be equally enthusiastic in support of Mr. J. H. Bulmer's view that aspiration of subperiosteal pus is an efficient method of drainage. Aspiration can in fact be very difficult, because the pus may be deep-seated and impossible to localize; nor is it a complete decompression, which requires drilling of the bone, and in any case it may well have to be repeated—an important consideration, particularly in children. Surgical drainage, on the other hand, is simple and produces a complete decompression. The bone must be drilled because pus under considerable tension is often present before a subperiosteal abscess forms. Prompt relief of pain and prevention of bone death is the result of surgery at this early stage of the disease.

With regard to the development of secondary infection and sinus formation after surgery I can only repeat that it has not been my experience. It certainly occurs in some patients when surgery is performed late (after about the third or fourth day of the illness), by which time the story of the disease has been written. I think this is the reason for the difference of opinion on this aspect of the problem. It is important, therefore, when referring to surgery to indicate when it is performed and what we mean by early and late. My own series indicated that the blood culture is negative in at least 50% of patients with acute osteomyelitis. It is an unreliable method of obtaining the organism for culture and sensitivity tests, and most laboratories cannot give a report in less than 48 hours, which is far too long to wait. A report on pus can be given in less than 24 hours, and is therefore of some practical value.

Finally, Sir, it is encouraging to note that most of your correspondents think that surgical decompression has an important part to play in the management of acute osteomyelitis in its early stages, as Trueta advocated 13 years ago[6] and supported by my own studies five years ago. The best method of treatment, despite all that has been written in the past, is now a controversy not so much among surgeons but rather between physicians and surgeons. Acute osteomyelitis is only one of many examples of this phenomenon, which is both stimulating (though sometimes frustrating) and inevitable when two such disciplines are involved.—I am, etc.,

National Kidney Centre

SIR,—As one of the founder trustees of the National Kidney Centre I would refer to the letter (22 July, p. 241) written by our medical director, Dr. S. Shaldon, and the news paragraph (p. 252) "Kidney Centre to Close." In this connexion I would draw your attention to a press denial by the trustees that the centre is to close. This is a decision which still has to be discussed by the trustees in the light of the resignation of Dr. Shaldon, which is to take effect from 1 July 1968. Obviously, if a suitable replacement for Dr. Shaldon could be found within a reasonable period of time the centre could continue to function, but if perchance this is not possible inevitably and regretfully it would have to close.

On 9 May last a meeting took place with representatives of the Minister of Health to discuss a Ministry of Health circular, No. H/A 190/14, where the Minister advised chairmen of medical committees of teaching hospitals and senior administrative officers that, while regional hospital boards have the power to refer patients to the National Kidney Centre and pay for treatment outside the N.H.S., it was the unanimous recommendation of the meeting that patients should not be referred, as this form of treatment should be based only on hospitals with full supporting facilities. At this meeting a plan to provide chronic dialysis in the United Kingdom based on the use of home haemodialysis, which would integrate the National Kidney Centre within the National Health Service, thereby making all the medical equipment and financial resources available to the National Health Service, was submitted for consideration, and to date no reply to this plan has been received.

The attitude of the trustees of the National Kidney Centre and its medical director has always been an unselfish one, and the result of Dr. Shaldon's research into home dialysis was quite staggering in its potential in the terms of numbers which could be treated. We therefore feel that by integration with the N.H.S. the maximum number of people suffering from this disease in the United Kingdom could receive benefit.

Regretfully, it is the complete lack of interest and approach to this matter which has developed cumulative frustration in our medical director which now results in his resignation. I would have thought that from a national point of view there must be a strong case for the retention of the National Kidney Centre until such time as a better form of development could be substituted in its place. Should the train of events now result in the eventual closure of the National Kidney Centre it would be a national tragedy.

The result during the last seven weeks has already proved disastrous, as the programme of the centre was to accept 60 patients by the end of the year. During the past three weeks any patients referred have not been accepted. By the end of the year, if the situation continues, some 30 prospective patients will die needlessly.

The National Kidney Centre has been established as a charitable, non-profit-making organization to provide artificial kidney treatment to as many patients as possible. The centre is concerned with providing treatment under ideal circumstances—one unit, one patient, at home and freed from the need for repeated hospital attendance, involving travel and pressure on bed space and nursing staff in the already overburdened Health Service hospitals. Though the effectiveness of artificial kidney treatment for those with incurably diseased or damaged kidneys is medically accepted beyond dispute, the National Health Service will be unable to provide this form of treatment for more than 5 to 10% of those who could benefit in the next few years. This means that 5,000 to 10,000 sufferers in this country will die unnecessarily in that time.

The National Kidney Centre was set up by a group of individuals who were dissatisfied with the Health Service plan and who wished to demonstrate an alternative approach —home dialysis—which would, through private funds, provide hope for the majority who are doomed to die and for whom no Government help is foreseeable.—I am, etc.,

MURRAY MEDWAY.

London N.3.

Amphetamine

SIR,—I have been most pleased to see in "Today's Drugs" on the prevention of motion sickness (12 August, p. 422) that you and your expert contributors say that any drug combination containing amphetamine is of itself open to objection. On turning overleaf (p. xii) I was dismayed to see an advertisement for an anti-obesity drug containing just such a combination.—I am, etc.,

Harrogate. T. G. REAH.

The "Pill" and Deep-venous Thrombosis

SIR,—Mr. K. Hæger and colleagues (19 August, p. 493) query the reliability of diagnosis of venous thrombosis in the Royal College of General Practitioners series of non-fatal cases discussed in the Medical Research Council report (6 May, p. 355) and other reported non-fatal cases. Their remarks do not apply to any of the reported deaths, all of which have come to necropsy, as will have most of those studied by the Dunlop Committee. Even in the Royal College of General Practitioners cases, as the same practitioners were caring for both patients and controls, an increased incidence of *something* (pseudothrombosis ?) has been found. Conversely, about 66% of deep-venous thromboses are not diagnosed in life[1] (my own observations agree) and it is as likely that the incidence is understated as overstated.

Interpreting broadly the term "coagulation patterns" in their last sentence, many studies have revealed a variety of changes in oral contraceptive users. To take one line of thought, your leading article (19 August, p. 449) says: "Platelet adhesiveness . . . has been shown to be increased in . . . venous thromboembolism." Puerperal venous thromboses are commonest about the tenth day, when both platelet count and platelet adhesiveness are maximal.[2] Platelet adhesiveness in the presence of encephalitogenic factor is increased in users.[3]

The platelet count in users is not increased.[4 5] This was claimed as evidence against any thrombotic risk, but Dr. J. Ll. Burton (22 July, p. 214) suggests that agglomerins (notably fibrinogen) cause rouleaux formation and raised erythrocyte sedimentation rate in users. Very likely they play a part in thrombosis. If, as your leading article suggests, platelet adhesiveness is an index of other blood changes it may in users connote a liability to thrombosis.—I am, etc.,

Surgery in Acquired Cardiac Disease

SIR,—Perhaps I may draw attention to an error in the report on my communication on the place of surgery in acquired cardiac disease at the Annual Meeting in Bristol in July (22 July, p. 233). I am reported as saying that: "Patients with mitral incompetence tended to run a more rapid downhill course after the *arrest* of symptoms . . . ." This should of course read "after the *onset* of symptoms . . . ." The change in the word of course completely alters the sense of the message.

I was anxious to point out that, since operations for mitral incompetence are more complex and hazardous than mitral valvotomy, patients should not be advised to have open operations unless the symptoms due to mitral incompetence were demanding. Thus I stated that many patients with mitral incompetence were capable of managing satisfactorily without surgery for a number of years and in them operation could often be postponed.—I am, etc.,

Royal Postgraduate
Medical School,
London W.12.

J. F. GOODWIN.

Protective Helmets and Traumatic Epilepsy

SIR,—I am very grateful for Mr. W. Bryan Jennett's helpful comments and information on traumatic epilepsy (29 July, p. 308). The following information may be of interest to him regarding his request for data on the incidence of head injuries in men wearing helmets.[1]

During a period of six months in a coal mining area where 16,732 were employed 324 men voluntarily reported to the colliery medical treatment centres injuries which had occurred to that area of the head normally covered by the helmet. Of these, 299 accidents occurred underground and 34 on the surface. The wearing of helmets was virtually 100% in underground workers; it was the exception rather than the rule for those working on the surface. The distribution of accidents which occurred at the underground working place, according to the site of the head injury, was 60% frontal, 17% side, 8% back, and 16% top of the head. Surface workers had a different distribution—namely, 24% frontal, 9% side, and 68% top.

These figures demonstrate the efficiency of the helmet in protecting the top of the head. Unfortunately, the design and wearing fashion of the helmet did not give the same degree of protection to the front of the head in underground workers. The helmet will only protect the head from injury if it is worn correctly and is designed to prevent those injuries which are foreseen. It must always be regarded as a second line of defence; accident prevention must be the primary aim.

Mr. Jennett is in error when he states that V. S. Caviness's conclusions[2] were based solely on a study of first world war gunshot wounds. In the statement I quoted from reference was made to the work of W. F. Caveness,[3] who investigated 356 young adult males who sustained head injuries in the Korean war campaign. Of these, 159 had non-missile head injuries. The report deals with the occurrence of epileptic attacks in the first 8 to 11 years following head injuries. W. F. Caveness stated, "While mode of injury is an important factor in the onset of fits, there is no significant difference between missile- and non-missile-injured men as regards the cessation of fits. A common clinical impression has been that the earlier the fits take place the less likely are they to persist. This has been held especially for those fits that occur within a few hours or days after injury. Conversely, it has been thought that those attacks that begin after one year seldom cease. In the current series neither is borne out."

Because Mr. Jennett's investigations[4] were of civilian head injury cases, his views are of great importance to those assessing prognosis, and especially his statement, "Early epilepsy (within a week of injury) has a 75% chance of permanent remission, but epilepsy developing later (whether or not there has been early epilepsy) persisted in more than 80% of 200 patients followed up for more than two years after their first fit."

Knowledge that seizures may cease can be an important factor when resettling patients. Unfortunately, to many managers the word "fit" is synonymous with unemployability. The possibility that seizures can cease may prevail on them to find suitable work, especially if the injury was the result of a works accident. Reduction of status and earnings are a deterrent to a proud craftsman from accepting the usual only available employment—for example, labouring. Acceptance of this work is made more likely when management undertake to upgrade a patient to his old skills if seizures cease permanently.—I am, etc.,

Recognizing Early Myxoedema

SIR,—The facial appearances of patients with well-marked myxoedema have long been familiar to clinicians, but the earliest manifestations of this are not easy to recognize.

Considering this problem recently, I realized that a personal method of assessment that I have long used might be of value to young general practitioners. (It is of no value to those seeing such patients for the first time.) It is, quite simply, the fact that on seeing such a patient my first thought has been: "Mrs. So-and-so is losing her looks."

This is most obvious in the 45–55 age group.

The woman whose face is getting plumper does not provide this thought, nor do the tragic sufferers from depression.—I am, etc.,

Leeds. A. U. MACKINNON.

Investigating Hypertension

SIR,—My letter (29 July, p. 306) was intended primarily to offer critical comment on your leading article (1 July, p. 4) which I had found not particularly helpful or informative. In that article you chose to quote Chamberlain and Gleeson's paper,[1] and I offered certain criticisms of their paper to which they have now replied (19 August, p. 495). Although they state that they "would not wish to advocate diagnostic nihilism but merely recognition of the limitations and potential dangers of a particular diagnostic technique," their comments are apt to be taken up and used as evidence against the value of aortography—as in your leading article and in recent correspondence elsewhere.[2] In my view their paper had certain limitations which should be recognized.

I share their view that the outcome of surgical treatment of hypertension may be unpredictable or disappointing—but I repeat the comment that the value of aortography should not be judged on this alone. If the procedure adds to the diagnostic data and enables one to exclude certain disorders (for example, fibromuscular dysplasia) and assists in obtaining a likely explanation for the hypertension (for example, "essential hypertension" with renal arterial anomalies) then there has been a useful gain. Further, I believe that medical management may be influenced in a number of ways by the aortographic findings—if only in providing a once-in-a-lifetime survey of the renal and intra-abdominal vascular tree and relieving the physician of the misgiving that he may be overlooking some important disorder. I have seen the sad consequences of inadequate investigation too often to feel confident in advising my patients after incomplete assessment.

Drs. Chamberlain and Gleeson chose to quote only our first and smaller series[3] in an implication that our series was somewhat unrepresentative (with a 9-to-1 male to female ratio, and two-thirds of the patients being Service personnel). The second paper which they mentioned[4] but did not quote in this context studies almost three times as many patients (341 as against 121), and 1 in 4 of the patients was female. As a matter of fact over the eight years which our unit has been working the proportion of Service to civilian patients is almost exactly 50%.

Their own work presented an interesting analysis of a retrospective study on a relatively small number of aortograms. We were not told of the period of time from which these results were collected, nor from how many hypertensive patients their 107 cases were selected—nor indeed how they were selected. Presumably since their text states "records of all aortograms were available and through these a retrospective study . . . was possible," the figure of 107 represents all patients subjected to angiography for hypertension at the Westminster Hospital since angiography was first introduced. It would be unusual if there had not been many hundreds, if not thousands, of hypertensive patients attending for advice, investigation, and treatment over this period—so my comment that their series was highly selected must stand.

Whether our own papers described a selected series of patients is not relevant to the discussion on angiography, though it might be to any discussion on hypertension. Any series is in fact initially selected by geographical, environmental, and other features—but we did describe the findings from a large number of unselected angiograms (since all patients under investigation for hypertension were angiographed) in a prospective study. This seems to me a much more acceptable method of assessing the value of the procedure.

If Dr. Chamberlain and Dr. Gleeson would care to visit our unit at any time they will be most welcome, and we would hope to show them that our work is not founded on "uncritical . . . aortography in the hope that this will provide a diagnostic answer that it is incapable of doing." Further, they would see that a large amount of evidence has accumulated over the past seven or eight years in support of our contention that renal dysplasia, often familial, is associated with much clinical disorder, including hypertension. Papers on these and other aspects of the work are in an advanced state of preparation.—I am, etc.,

P. W. ROBERTSON.

Progestin Therapy of Breast Cancer

SIR,—Dr. B. A. Stoll (5 August, p. 338) has to be congratulated for his very worthwhile attempt at screening the efficacy of various progestational preparations in the treatment of advanced breast cancer. The paucity of satisfactory responses in his series of seven compounds tested should not discourage the search for more effective agents. The smallest change in the chemical structure of these steroids can markedly alter their clinical efficacy. For instance, the negative impression gained in the earliest trial in this country with norethisterone oenanthate was dispelled by a very similar compound having a shorter side chain and giving improved clinical results. Similarly the addition of 5 mg. oestradiol benzoate to progesterone 50 mg. by daily injection proved successful in 7 of the 15 cases with breast cancer treated by Landau *et al.*[1]

In this department further experience was gained from the combination of progesterone (19-nor-17α-hydroxyprogesterone caproate) 100 mg., with oestradiol valerate, 30 mg. Twenty-five patients (four premenopausal) with advanced cancer of the breast in whom previous surgery, radiotherapy, oestrogens, and androgens have either failed to arrest the progress of the disease or ceased to be effective were treated with this compound for periods of one to 14 months, receiving intramuscular injections weekly, later increased to twice weekly. In 8 cases (32%) a moderate to good response was noted with regression of visible skin and glandular neoplastic infiltration, disappearance of oedema, and amelioration of general conditions. In no case, however, did the arrest of the disease last for a period longer than ten months. No untoward side-effects were noted except in one patient who did not tolerate the agent on account of nausea. A detailed report on this trial will be published shortly.

Of the possible modes of action of progestins in breast cancer listed by Dr. Stoll probably the most important—that is, the action of progestational compounds on target organs via changes in mesenchymal structures so prominent among the known effects in endometrial carcinoma—has not been mentioned.

Theorizing in the context of the rationale of treatment is very important, as none of the synthetic progestational compounds possesses all of the known properties of natural progesterone, and, since the various properties are present in varying degrees in the compounds on trial, different criteria must be employed for testing their efficacy.

In this regard, according to Swyer *et al.*,[2] in premenopausal women only the cessation of menstruation is of value to give data for a probit analysis. Other tests such as vaginal smear changes, depression of karyopyknotic index, inhibition of ovulation, etc., do not help in establishing potency ratios with fiducial limits of error. Effects on vaginal smears are not likely to be more reliable in this regard in post-menopausal women, and caution should be exercised in drawing conclusions for the selection of patients suitable for this type of hormone therapy.

G.P.s and Health Centres

SIR,—In view of the interest in health centres, we circularized all general medical practitioners in the London Borough of Redbridge (population 248,000), asking whether they would be prepared to consider transferring their practice premises to a health centre, assuming that the proposed site of the health centre was satisfactory.

Type of Practice	No. of Replies	No. of Practices	Practices Willing to Consider Transferring Sole Surgery Whole Time	Practices Willing to Consider Transferring Main Surgery Whole Time	Practices Willing to Consider Transferring Branch Surgery Whole Time	Practices Willing to Consider Transferring Branch Surgery Initially and Main Surgery Later	Practices Unwilling to Consider Transfer	Other
Single-handed, sole premises ..	28	28	15	—	—	—	10	3
Partnership, sole premises ..	22	12	6	—	—	—	5	2
Single-handed, more than one surgery ..	3	3	—	—	—	2	—	1
Partnership, more than one surgery	20	13	—	5	4	—	4	—
Totals ..	73	56	21	5	4	2	19	6

One hundred and forty-seven questionaries were despatched and 73 replies (50%) were received. The information received is shown in the Table.

We do not claim statistical validity for the information, because we do not know the views of the 50% who did not reply. It is interesting to note, however, that 32 out of the 56 practices which replied (57%) were willing to consider some form of health-centre practice. It is possible that many of those who did not reply were unwilling to commit themselves at an early stage, but, if experience in other areas is any guide, once a health centre is built there are often requests from general practitioners to be allowed to participate.—We are, etc.,

I. GORDON.
A. SHAW.

Importance of Medical Administrators

SIR,—It would be true to say that since 1948 medical administrators at hospital level have had a very thin time, in many cases being unwanted by management committees and their posts being dispensed with by hospital boards. Those who remained, and with more than a minimal number of sessions allocated to administration, found these sessions priced at an appreciably lower level than their clinical sessions.

It is therefore encouraging to note the increasing, if tardy, recognition of the importance of medical administration and the need for appropriate remuneration and training, as expressed in the Memorandum on the Current Problems of Hospital Medical Staff (*Supplement*, 13 May, p. 93, para. 32).

Likewise, it is welcome news that the Health Departments and the professions are agreed on the importance of this work, and are united in a desire to see an increase in the number of doctors qualified by training and experience to be medical administrators, as expressed in the Joint Second Report on the Negotiations with N.H.S. Hospital Doctors and Dentists (*Supplement*, 19 August, p. 119, para. 8).—I am, etc.,

NORMAN V. WILLIAMS.

Cefn Mably Hospital
St. Mellons, nr. Cardiff.

Opportunities in British Medicine

SIR,—I read in the Australian-printed edition of the *B.M.J.* that the Ministry are to woo doctors back from overseas (15 July, p. 128). The very fact that the Australian edition exists is a pitiful commentary on the Ministry's previous efforts related to practice in Britain. After considerable experience of English general practice and lately sufficient sight of Australian practice in a town of some 40,000 people, may I offer some advice to two sections of your readers. Firstly, to any young doctors who are contemplating English general practice: Don't! Give up the idea and leave as soon as possible.

Secondly, to the Ministry officials who are going overseas: You may possibly have some success with the older migrants who have deep roots in Britain, provided that you offer them access to hospital in some reasonable form. They will, however, look at you in amazement when you explain that the immense experience they have gained overseas will be rewarded by loss of seniority.

There are some quite good administrative posts overseas, so it is to be hoped a second Ministry team is not necessary to get the first one back.—I am, etc.,

Albury, N.S.W.,
Australia.

F. W. B. BREAKEY.

Points from Letters

Temporary Residents and the Casualty Department

Dr. G. W. GRIFFITHS (Bangor, N. Wales) writes: Often in areas whose temporary population is increased owing to its popular holiday appeal patients (young and old) use the overburdened casualty/accident units as "casual surgeries." By this I mean patients (and I refer particularly to children) who are brought in with non-urgent, non-traumatic illnesses.

For this service the general practitioner claims a fee—quite rightly and properly. The poor casualty officer, however, cannot claim even a shilling—and has a further burden of responsibility to carry on his often relatively inexperienced shoulders.

Infectivity of Scabies

Dr. J. O'D. ALEXANDER (Glasgow) writes: I observe with regret that my colleague Dr. R. W. Carslaw (12 August, p. 437) has misinterpreted my remarks on the diagnosis of scabies (17 June, p. 766). I said, "Above all it depends on the constant suspicion that an itchy patient may have scabies, even though the evidence is scanty." This is not advocating the *treatment* of a case of itching as scabies without confirmation. Suspicion will make the physician even more careful in his examination. It will prompt him to look for further evidence and critically to assess what evidence he has. The risk of not diagnosing a case of scabies will be reduced. I am in entire agreement that treating all cases of itching as scabies as a blanket cover for possible errors is unwise. I would go further and say it is foolish, because it creates far more difficulties than it solves.

On the other hand, Dr. Carslaw's remarks about the infectivity of scabies should not pass without comment. I think he is perhaps stretching a point when he says that infectivity from clothing and bedclothes is a myth. Mellanby[1] showed quite clearly that there was a risk if volunteers slept in the beds previously occupied by scabetics. The risk was small (he put it at 1 in 200) but nevertheless could occur. It should not therefore be stated to be a myth.

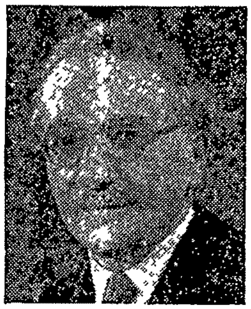
Obituary Notices

TERENCE EAST, M.A., D.M., F.R.C.P.

Dr. C. F. T. East, formerly consultant physician and physician-in-charge of the cardiological department at King's College Hospital, and consultant physician to the Woolwich War Memorial Hospital, London, died very suddenly at his home in North Cornwall on 27 August. He was 73.

Charles Frederick Terence East, son of Dr. C. H. East, of Malvern, was born in Malvern on 20 June 1894, and was educated at Winchester and New College, Oxford. His studies were interrupted by the first world war, during which he served as lieutenant in the Northamptonshire Regiment and was twice severely wounded. After demobilization in 1918 he returned to Oxford, and graduated B.A. in 1919, winning the Welch prize, and proceeded M.A. two years later. For his clinical studies he entered King's College Hospital Medical School in 1919, having been awarded the Burney Yeo scholarship. He graduated B.M., B.Ch. in 1921, and took the Conjoint diploma the same year. He also studied at the Universities of Freiburg and Lausanne. He took the M.R.C.P. in 1922, and was awarded the Murchison scholarship by the Royal College of Physicians. After serving early house appointments at King's College Hospital, he was appointed medical registrar in 1923, and the following year was Radcliffe Travelling Fellow, University College, Oxford. In 1924 he was appointed concurrently junior physician, senior medical tutor, lecturer in morbid anatomy, and curator of the museum at King's College Hospital.



[King's College Hospital Gazette

Terence East had early developed a special interest in cardiology, and on the retirement of Dr. Harold Wiltshire in 1924 East took over the work of the department, becoming physician-in-charge. In 1931 he was appointed full physician, and in 1945 he became senior physician and director of medical studies in the medical school. He proceeded D.M. in 1927, and was elected F.R.C.P. in the same year. He also held additional appointments of consulting physician to the London County Council, the Woolwich War Memorial Hospital, and the Bute Hospital, Luton.

He was an examiner in the final B.M., for Oxford University, was a councillor of the Royal College of Physicians in 1949–50, elected censor in 1951, and senior censor in 1954. He gave the FitzPatrick lecture in 1956 and 1957, quoting freely from early authors whose works on congenital heart disease he had read in the original Latin. He gave the first Wiltshire lecture at King's College Hospital in 1960, a year after he retired, taking as his title "Forty Years of Cardiology."

Terence East was generally regarded as a somewhat lonely man, but he had a number of close friends from his student days at Oxford and King's. A physician of the old school, he paid great attention to accurately described physical signs, which enabled him to build up a diagnosis in a logical manner. He was keenly interested in teaching, and it was unfortunate that his habit of speaking in a low voice, almost as if talking to himself, enabled only those immediately around the bedside to hear what he said. There was always great competition to be his house physician, and a number of modern cardiologists owe their early interest in heart disease to him.

Sensitive and kindly, Terence was a countryman at heart. For many years he lived near Wimbledon Common, and it was his habit to walk there before breakfast to study plant and bird life. He was a keen botanist, and many King's men will remember with pleasure visits to the Chelsea Physic Garden, where he would hold forth on the properties of the "excellent herbs" grown there, with stories of those whose names were associated with them.

He retired to St. Merryn, where he could pursue his enjoyment of the pleasures of the country and watch birds, sail, read, and paint. He is survived by his wife, his daughter, and two sons.—R. S. B. P.

H. O. BLAUVELT, M.D., C.M., F.R.C.S.

Mr. H. O. Blauvelt, formerly senior surgeon to Chase Farm Hospital, Enfield, and surgeon to the North Middlesex Hospital, Edmonton, died on 7 August. He was 70.

Hugh Osmond Blauvelt was born on 18 August 1896 at Windsor, Nova Scotia, and spent his early years in Canada. He graduated M.D., C.M. from Dalhousie in 1918 and became a lieutenant in the Canadian Army. After demobilization he practised at Lockeport, Nova Scotia, for a few years and then came to England. He took the Conjoint diploma in 1927 and the F.R.C.S. in 1930.

He was appointed to a surgical post at the North Middlesex Hospital, and flourished in the progressive atmosphere where hard work was rewarded with plenty more work to do. His ascent of the professional ladder was not by any academic steps but by learning the art of surgery from leading exponents on the staff of the hospital such as Ivor Lewis, R. L. Galloway, and K. A. K. Hudson. At this time he wrote several good papers, and one of them is commemorated in Blauvelt's sign (subcutaneous fat necrosis in acute pancreatitis).

For a brief period he went to Middlesbrough as honorary assistant surgeon to the North Ormesby Hospital, but he soon returned to London to rejoin the staff at the North Middlesex Hospital as a senior member. He later moved to Chase Farm Hospital, Enfield, where he built up his surgical reputation. From his surgical colleagues in the municipal hospital service he learned his art, and he was a safe surgeon for whom mere feasibility alone was never the indication to operate. He outshone his colleagues in his ability to teach, and for years his fellowship classes were a Mecca for surgical postgraduates.

After retirement he continued to do some surgical work in the Highlands and Islands service. He enjoyed country life and fishing at Drumnadrochit, and was able to devote time to the hobby in which he excelled—wood-carving and the restoration of old furniture.

Hugh Blauvelt was a man of high principles who would take a firm stand when he thought fit. He had no enemies and was widely respected by colleagues and patients. By his death British surgery has lost a fine exponent and numerous folk in Enfield and Edmonton a trusted friend. His last short illness was clouded by the sudden loss of his wife. To his son and daughter we extend our sincere sympathy in the loss of their parents.—C. A. B.

W. K. HAMILTON, M.B., CH.B., F.R.C.S.ED.

Mr. W. K. Hamilton, former consultant ear, nose, and throat surgeon at Walsall General Hospital, and consultant ear, nose, and throat surgeon to the Guest Hospital, Dudley, and to other hospitals in the Dudley and Stourbridge group, died suddenly on 11 August, aged 67 years.

William Keith Hamilton was born in Timaru, New Zealand, on 23 December 1899. His education was interrupted by the first world war; he joined the Army at the age of 16 years, and had risen to the rank of captain when he was demobilized. He returned to New Zealand, and entered Otago University Medical School, graduating M.B., Ch.B. in 1924. Shortly afterwards he came to Edinburgh, and became a Fellow of the Royal College of Surgeons of Edinburgh in 1927. After a period in general and urological work in London he went to Oswestry, and for three years was assistant to Sir Robert Jones at the Robert Jones and Agnes Hunt Orthopaedic Hospital. He returned to New Zealand on the death of his mother, but after three years went to America for further postgraduate study, working in Chicago and at the Mayo Clinic at Rochester, New York. He then returned to England and took up the specialty of otolaryngology, studying at Golden Square Hospital, Bradford Eye and Ear Hospital, and the Royal Hospital, Wolverhampton. In February 1937 he became consultant ear, nose, and throat surgeon to the Guest Hospital, Dudley, and the Walsall General Hospital. He was a member of the British Association of Otolarygnologists and a member of the Midland Institute of Otology.

To Bill Hamilton the two things in life that mattered most were his work and his family—he was devoted to both. He was a quiet man endowed with great charm. He died suddenly while on his way to the coast of North Wales, on holiday with his family.

He leaves his widow and three children, the eldest of whom, Philip, has recently qualified as a doctor. We extend to them our deepest sympathy.—R. G. H.

L. MORRIS, M.D., F.R.C.S.

Mr. L. Morris, formerly senior orthopaedic surgeon to the Leicester group of hospitals, died at his home on 19 August. He was 67.

Leslie Morris was born on 23 June 1900, and was educated at the school in Ashton-under-Lyne where his father was headmaster. Entering Manchester University, he graduated M.B., Ch.B. in 1923, and took the Conjoint diploma the following year. In 1925 he took the F.R.C.S. The M.D., with commendation, was conferred upon him by his university in 1928 for a masterly thesis on the anatomy of the Gasserian ganglion and the treatment of fifth-nerve neuralgia by alcohol injection using the anterior approach to the ganglion. This was at the time when recognized neurologists were still employing the somewhat ineffectual lateral approach to the nerve divisions. His interest in the subject was maintained for many years, and his success with his own technique was such that patients were referred to him for treatment long after he had become established as an orthopaedic surgeon.

His Leicester appointment came after periods as assistant resident surgical officer in Manchester Royal Infirmary, and as registrar at the Royal National Orthopaedic Hospital, London. At this time he developed a lifelong admiration for Sir Robert Jones, and throughout the years Sir Robert's profile in plaster occupied a prominent place in his private consulting-room. Morris was responsible for the initiation of the orthopaedic section of the Leicester school clinic in 1930, and for its future development. In addition to his main appointments at the Royal Infirmary and the General Hospital at Leicester he was senior orthopaedic surgeon to the Kettering General Hospital, had a close association with Melton Mowbray and the Miners' Rehabilitation Centre at Higham Grange, and was an associate surgeon at Harlow Wood Orthopaedic Hospital. For many years he was the consultant surgeon to Leicester City Football Club, rarely missing a home match. He retired just over two years ago.

A conscientious surgeon whose name became a household word, Leslie was rarely late for any appointment. He was loyal and true to his friends, and a friendship once made was lasting, but to those holding a different viewpoint he could be firm and expressive without being impolite. Outside his professional work his great interests were in music, and as a collector of antiques and pottery. He played no instrument himself, but as a regular visitor to the Royal Opera House in Covent Garden with his wife, who shared his enjoyment, he had an outstanding interest in opera and the ballet. In all that he did he was sincere, and he was devoted to his family of four married daughters, his home, his garden, and to the countryside of England, especially to his beloved Cornwall. —E. R. F.

S. G. CORNER, M.A., M.D., D.O.M.S.

Dr. S. G. Corner, a former Essex ophthalmic surgeon, who had been living in Umtali, Rhodesia, since 1948, died on 27 July, aged 87.

Samuel Gordon Corner was born in Inverness of Highland parentage on 12 January 1880, and was educated at the Inverness Royal Academy. He entered Edinburgh University, and in 1902 took the M.A., his studies having been interrupted by service with the University contingent of the Imperial Yeomanry in the South African war, an episode in his life which was to leave a lasting liking for that country. In 1906 he graduated M.B., Ch.B., and after serving as house-surgeon at the Essex County Hospital, Colchester, he worked for a time in Coggeshall before moving to Chelmsford, where he settled down in general practice. He proceeded M.D. in 1910. The first world war saw him again in South Africa, this time as a captain in the R.A.M.C. After demobilization he returned to his practice in Chelmsford. Between the wars he began to specialize in ophthalmology, after which he gave up general practice. He took the D.O.M.S. in 1940, and held an honorary appointment at Moorfields Eye Hospital, London. From 1937 to 1946 he was chairman of the Mid-Essex Division of the British Medical Association. His connexion with Essex and Chelmsford lasted for over forty years.

During the second world war he volunteered for active service, but was turned down on account of age. However, he was appointed lieutenant-colonel in the medical section of the Home Guard.

About 1948 Corner moved to Umtali, in Southern Rhodesia, where he continued to do ophthalmic work, and he lived there until his death. He had been a keen shot in his early days (he even carried his shotgun to the South African war), and was a good golfer. All his life he had a love for natural history and botany, the basis of which was laid in open-air studies in Inverness and the Highlands. On his last visit home he was very pleased when the director of the Edinburgh Botanic Gardens accepted a collection of plants made on his tours of Rhodesia. His house was full of memories of Essex and Scotland, and was frequently visited by Essex people who had settled in Rhodesia. He married Miss Gladys Benham, of Colchester, who died in 1928. He is survived by his daughter and by his son.—Wm. C.

J. T. W. writes: Sam Corner came to Chelmsford about 1912, and established himself successfully as a general practitioner. He was exceedingly generous to the younger men, and purposely cultivated a delightful habit of calculated forgetfulness. His patients all adored him, and he was always at their beck and call. His hobbies were books and golf, and, on his holidays in his native Scotland, fishing. A man much loved and admired by us all in Chelmsford, he retired from his work in Essex after the inception of the National Health Service and went to live with his daughter in Rhodesia, where he continued to work as an ophthalmologist.

W. J. ADAM, M.B., CH.B.

Dr. W. J. Adam, for many years in general practice in Marden, Kent, died in Eastbourne on 24 July. He was 71.

William James Adam was born in Aberdeen, the third son of Dr. Wilson Adam, who practised in Crown Street, Aberdeen. He was educated at Robert Gordon's College and at Aberdeen University. His medical studies were interrupted by the first world war and he saw service as an ambulance driver in Mesopotamia. After the armistice he returned to Aberdeen and graduated M.B., Ch.B. in 1922. For six years he acted as assistant to Dr. Oliphant in Bucksburn, Aberdeen, then obtained his own practice in Marden in 1928, where he remained until his retirement in 1958.

Dr. Adam had many of the attributes that make for success in family practice—a deep understanding of people and of the effects that illness could have upon them and their families, an unerring ability to tell when patients—especially children—were really ill and required assistance beyond what he could give, an easy manner and capacity to deal happily with patients from all social classes, and a deep knowledge of the community in which he worked. During the last war he held the rank of captain in the R.A.M.C. and was responsible for the medical training of Home Guards and Red Cross personnel in the Marden area. In his retirement he turned to gardening and philately, building up a large and carefully selected collection of stamps. Dr. Adam is survived by his wife.—J. K. R.

D. M. FORSTER, M.B., CH.B.

Dr. D. M. Forster, formerly in general practice in Brownhills, Staffordshire, died at his home on 21 June. He was 54.

Donald Makepeace Forster was born in Exeter on 9 April 1913, and was educated at Dudley Grammar School and at Birmingham University Medical School, graduating M.B., Ch.B. in 1940 and qualifying with the Conjoint diploma in the same year. After holding house appointments at the Queen's Hospital, Birmingham, he entered the Indian Medical Service with the rank of captain. In 1942 he married Miss E. M. Murdoch, and four years later joined Drs. Bradford and Patterson in practice at Brownhills. In addition to his duties as a general practitioner he became honorary divisional surgeon to the St. John Ambulance Brigade and police surgeon to the Brownhills subdivision of the Staffordshire County Constabulary. He was a founder member of the Brownhills Rotary Club and later its president in 1961–2. He was elected chairman of the Walsall Division of the British Medical Association in 1966.

Dr. Forster was a friendly and instantly likable man, whose qualities of kindness and good humour became even more evident on closer acquaintance. He had an active and inquiring mind, which he applied not only to his daily work but to all medical affairs and to his varied hobbies. In addition to being a keen fisherman he also interested himself in photography, music, and electronics, and in 1958 won first prize in the electrical section of the doctors' hobbies exhibition by building an electronic organ. He will be greatly missed by his patients, of whom he took such thoughtful care, never sparing his own health in order to look after theirs. His colleagues all regarded him with affection, and admired in him the rare qualities which made him a family doctor of such high calibre.

He is survived by his widow, a son recently qualified in medicine, and a daughter, to whom we extend our sympathy.—J. P. L.

J. C. WILLIAMS, L.M.S.S.A.

Dr. J. C. Williams, a former medical officer to the British Shipping Federation, died in London on 13 July. He was 62.

John Claude Williams was born in Cape Town on 12 August 1904, and was educated at Malvern College and Worcester College, Oxford. He became a licentiate in medicine and surgery of the Society of Apothecaries of London in 1933, and was elected to the Livery of the Society of Apothecaries in 1935. He set up in private practice in Devonshire Street, London, where many eminent personalities became his patients. The outbreak of the second world war found him in the U.S.A. He returned immediately, booking the first available passage home to join the Emergency River Service. For the last two or three years of the war he was medical officer in one of H.M. cable-laying ships, and although he was never forthcoming about his exploits either to members of his family or to his friends, he took part in at least one memorable attempt to sail a disabled tanker back to the United Kingdom. After the war he joined the Prison Service as a medical officer, and was concerned with the Heath, Haigh, and Christie trials. He found the strain of this work, and attendances at executions, too much for him, and after resigning from the service he joined the British Shipping Federation as a medical officer, where he remained until his health failed, and he was able only to manage an occasional locum.

He had a wide circle of friends who enjoyed his unfailing sense of humour. He will be sadly missed by all those who knew him. He died a bachelor.—P. A. W.

G. J. MURRAY, M.D., M.R.C.P. D.T.M.&H.

Dr. G. J. Murray, senior physician at Hexham General Hospital, died on 10 August, at the age of 57.

Gerard John Murray was born on 9 December 1909, at Blackhill, Co. Durham, and was the elder son of Dr. John Murray, a well-known general practitioner. He received his education at St. Joseph's College, Dumfries, and later at the medical school of Durham University at Newcastle upon Tyne, graduating in 1932 with second-class honours, and proceeding M.D. two years later. He spent the next five years in various hospital appointments, and in 1937 he joined the Colonial Medical Service and spent two years in Uganda. During his student days he had, like several of his friends, joined the R.N.V.R., and at the outbreak of the second world war he was mobilized, and spent the next six years with the Royal Navy, serving in the hospital ship *Oxfordshire* as pathologist, with the rank of surgeon lieutenant-commander. Later he was attached to the Wentworth Hospital in Durban, and finally to the Royal Naval Hospital at Newton Abbot, Devon, and while there was admitted M.R.C.P. in 1943. On demobilization he came to Newcastle, and became a medical registrar at the Royal Victoria Infirmary, but his previous experience abroad seemed to develop a restlessness in his nature and he joined the Esso Oil Company as chief medical officer, and travelled extensively. He took the D.T.M.&H. in 1946. With the inception of the National Health Service in 1948 he was appointed physician-in-charge to the Hexham group of hospitals in Northumberland.

I was privileged to know Gerry Murray very well. Our friendship began in the early days of our undergraduate training, and continued throughout the years. As visiting paediatrician to his hospital I saw him regularly, and we discussed paediatric and other problems with mutual interest and enjoyment. He was a very capable and kind doctor; his manner was always serene and calm, and he never appeared to be ruffled, even in the most urgent situations. He was always accessible to his medical and nursing staff alike. In his student days he was a very good all-round sportsman, but the demands of his work restricted these pursuits, although he did find time occasionally to continue with his latter sport of yachting, especially at Bassenthwaite.

In the past few years he was dogged persistently by ill-health, which he bore with great patience and fortitude. A man of strong religious convictions, his faith was a source of great comfort and strength to him. Towards the end of his life he was almost completely disabled, and yet there appeared to be no rancour, but the calm acceptance of fate. He was indeed a gentle man. To his wife and family, who formed such a happy unit, we extend our deepest sympathy.—E. G. B.

M. L. KAIN, M.D.

Dr. M. L. Kain, an American anaesthetist engaged on research training at the University of Leeds, his wife and son, together with his wife's parents, were killed instantly in a motor accident in Holland on 9 August. He was 27.

Martin Lee Kain was born in 1940, and graduated M.D. in 1963 from the University of Chicago. He was an intern at the Mary Hitchcock Memorial Hospital in Hanover, New Hampshire, after which he proceeded to a two-year residency in anaesthesiology at the Presbyterian Hospital, New York, under Dr. E. M. Papper. He then sought a formal training in research, and was perhaps the first American anaesthetist to do so in England. In June 1966, he came to the department of anaesthesia of the University of Leeds, and registered as a Ph.D. student. His wife had her Master's degree in history, and she also registered as a Ph.D. student in the department of modern history of the same university.

At an early stage of his career it was apparent that Martin Kain was a man of exceptional ability. He had set his sights on a career in academic anaesthesia, and his talents were well suited to this. He was highly intelligent, had a quick mind, and an immense capacity for sustained hard work. He soon grasped the fundamentals of experimental design, and at an early stage was initiating his own studies. He was a competent linguist, fluent in German, and well versed in Russian, Spanish, French, and Italian. He will be well known to many for his published translation of one of the classical papers of von Neergaard and Wirz. He was also an amateur musician, and played regularly in a string quartet. Dr. Kain combined his exceptional talents with a delightful personality. His courtesy never left him, and his ability was unusually concealed beneath an exterior of genuine modesty, with his cheerful and easy manner giving little hint of his acute perception.

Those who knew Martin Kain in this country have experienced a tremendous personal loss. However, their loss is no greater than that of anaesthesia as a whole. The specialty has lost a man who was surely destined to be an international leader in the years to come. His many friends in this country extend their deepest sympathy to his parents, and to the relatives of all those concerned in this tragic accident.—J. F. N.

E. B. VERNEY, M.A., M.D., F.R.C.P. F.R.S.

G. B. writes: When Basil Verney (obituary, 2 September, p. 621) came to St. Bartholomew's from Cambridge for his clinical work he soon came under the influence of that remarkable teacher Dr. J. H. Drysdale, and this influence was apparent throughout his professional and personal career. The brilliance of his laboratory work, both in conception and in technique, is a matter for others to assess. Sufficient it is to mention that he made a unique contribution to the understanding of the mechanisms controlling the secretion of pituitary hormones concerned in urinary excretion.

He was a firm opponent of intellectual compromise and a champion of scientific truth, for which he would have fought to the death. He was once sued by the antivivisectionists for cruelty, but was entirely vindicated. There hung in his laboratory for years a framed and faded poster from the *Star*: "Professor *v.* Dog Result," a cherished souvenir.

As an examiner in pharmacology for the third M.B. he gained a reputation for strictness. He was strict, but only to the point of affirming that a candidate must know the dangers to his patients of drugs and measures, and never to the extent of insisting upon a knowledge of irrelevant minutiae.

When Verney became house-physician at Shadwell I was physician there, and Ruth Conway was resident medical officer and Basil's senior. This collaboration had a happy outcome, for they later became engaged, and I had the pleasure of being best man at their wedding, the first milestone in a long and valuable friendship. Through all the years since, a scintillating characteristic of Basil's companionship has been a keen sense of humour, never far from the surface.

A modest man, retiring by disposition, he never hungered after money or worldly status. He bore through life the shining grace of a personality true to the uttermost depth, and to have known him was a privilege and a joy.

News and Notes

EPIDEMIOLOGY

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **19 August** (No. 33) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included). Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

MEDICAL NEWS

First Woman President

Dame KATHLEEN LONSDALE, F.R.S., has been elected president of the British Association for the Advancement of Science. She will preside at next year's annual meeting. Dame Kathleen is professor of chemistry and head of the department of crystallography at University College, London.

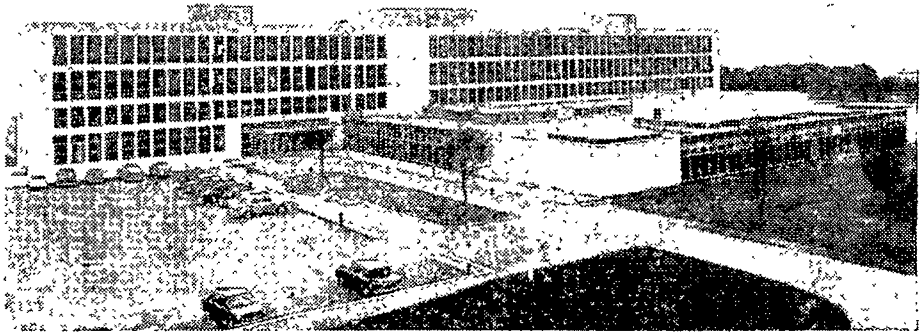
Sir PETER MEDAWAR, F.R.S., director of the National Institute for Medical Research, has been nominated president-elect of the association for 1968–9.

Postgraduate Medical Education

At a meeting on 21 July the Central Committee on Postgraduate Medical Education (see *B.M.J.*, 24 June, p. 833) incorporated "(Great Britain)" in its title, in recognition of its concern with Scotland as well as England and Wales. It decided to invite a representative of the Royal Medico-Psychological Association to attend its meetings. A preliminary paper bringing together members' views on the organization of post-registration training (the first three years) was discussed. The Committee agreed to invite the Ministry of Health to send representatives to the next meeting to consider the relation of postgraduate training to the career structure of the hospital service.

New Plastic Surgery Unit

A plastic and reconstructive surgery unit, which has cost about £1m. to build and equip, was opened last week at Canniesburn, Glasgow. It consists of a main block containing wards, outpatient department, staff and lecture rooms, and an adjoining single-storey area with operating-theatres and dental, *x*-ray, and other special departments. There are 138 beds. Facilities include four in-patient theatres with intensive care unit, an outpatient theatre and day-stay ward, maxillofacial department, and suite of consulting-rooms. Provision is made for research. The unit is designed to ensure privacy. For



patients arriving by ambulance a special reception department with direct access to the wards has been provided at the rear of the building. The completion of the project brings together facilities hitherto spread throughout the region.

Psychotropic Drugs

The Committee on Safety of Drugs published its sixth note in the adverse reaction series on 8 September. It draws attention to the large number of prescriptions for psychotropic drugs—43 million were issued by general practitioners in the N.H.S. during the three years ending June 1967—and states that 1,200 reports of suspected adverse reactions to these drugs, with 91 deaths, were received in the three-year period.

History of Medicine

The sixth British congress on the history of medicine was held from 6 to 9 September at the University of Sussex, Brighton. The theme was "Medicine and Science in the 1860s." At the inaugural session an address was given by Dr. DOUGLAS GUTHRIE, president of the British Society for the History of Medicine. An exhibition of illustrations, arranged by the Wellcome Historical Medical Museum and Library, was on view throughout the congress.

Health Services in Scotland

Expenditure on the National Health Service in Scotland has risen about 52% in the last 10 years according to the 1966 report of the Health and Welfare Services (H.M.S.O., Cmnd. 3337, 9s.) In 1965–6 the gross cost of the Service was about £145m., compared with £130m. in the previous year. Excluding capital expenditure, the cost of the hospital and specialist services was £78m., an increase of £7m. The hospital building programme "maintained its impetus," the total capital investment in hospitals being nearly £10m.

In 1966 the birth rate (18.6 per 1,000 population) was the lowest since 1956. The illegitimate live birth rate rose to 6.4% (provisional), the highest recorded since 1946. Stillbirths fell by 246, giving the lowest stillbirth rate so far recorded (16.2 per 1,000 total births). The infant mortality rate (23.2 per 1,000 live births) was slightly higher than the record low rate in 1965 (23.1). In 25 local authority areas fewer than 10% of births took place at home, and in 21 other areas fewer than 20% of births were home confinements. The total number of births in these 46 areas accounted for 90% of the total births in the country.

Deaths from lung cancer rose from 3,009 in 1964 to 3,120 in 1965, the increase among women being proportionately greater. Bronchitis accounted for 2,066 male deaths (83 per 100,000) and 788 female deaths (29 per 100,000). The figures were little better than the all-time high of 2,171 and 881 respectively recorded in 1963. The report notes "disquieting trends" in the admission of people suffering from the effects of poisons, usually self-administered. By far the largest increase occurred among young women. A tendency towards an increase in cases of otitis media and mastoiditis is noted.

Expenditure on mental health continued to rise more rapidly than in any other field of local authority health and welfare work during 1965–6, with an increase of 28% over the preceding year. The number of patients admitted to mental hospitals with a diagnosis of alcoholism was the highest recorded (2,755). According to the report more than a quarter of all male admissions to mental hospitals are for alcoholism.

Hospital geriatric services are stated to have been increased, with special emphasis on rehabilitation and return to life in the community. Residential accommodation in local authority welfare homes rose from 7,428 places at the beginning of 1966 to 7,639 places at the end of the year.

Between October 1965 and September 1966 640,950 patients were discharged from N.H.S. hospitals. This was 10.9% more than in 1960–1. The average weekly cost per inpatient was £23 5s. 5d., compared with £21 4s. 1d. in the previous year, and the average length of stay for each period of treatment was 31 days.

The number of principals providing general medical services was 2,594, compared with 2,618 at the end of 1965. As a result, the average number of patients in each doctor's list rose from 2,066 to 2,089. At September 1966 3,478 doctors were employed in hospitals, compared with 3,118 in 1961, an increase of 11.6% in five years. There were 1,335 consultants, an increase of 32.5% in the same five-year period. The number of nurses and midwives was higher than ever before.

In 1966 27.53m. prescriptions were dispensed, an increase of 7.5% over the figure for the previous year.

Appendices to the report give details of research programmes supported by Exchequer funds, of hospital building schemes completed and in progress, and statistical tables.

News in Brief

The provisions of the Road Safety Act referring to drink and driving will come into force on 9 October.

Grants and Awards

Grants for research projects at Glasgow University include £9,000 from the British Empire Cancer Campaign for Research for work in the biochemistry department and £7,500 from the Tobacco Research Council for research in the department of medical cardiology, Royal Infirmary, into smoking and lipid metabolism.

Coming Events

Davos Medical Association.—International symposium on tuberculosis, climate, asthma, and chronic bronchitis, 8–10 October, Davos. Conference fee about £3. Applications by 15 September.

Systematic Course in Psychological Medicine and Related Basic Sciences 1967–8.—Designed to provide instruction for Parts 1 and 2 of the D.P.M., starts 21 September. Details from Physician Superintendent, Runwell Hospital, Wickford, Essex.

Norfolk and Norwich Institute for Medical Education.—Symposium on pitfalls in rheumatic disease, 23 September, St. Michael's Hospital, Aylsham. Course recognized by Cambridge University Postgraduate Medical School for purposes of allowances to general practitioners.

Chemotherapy of Tuberculosis in Developing Countries.—Symposium sponsored by Smith and Nephew Associated Companies Ltd., 25–27 September, Royal College of Surgeons of England, Lincoln's Inn Fields, London W.C.2. Attendance is primarily limited to those with special knowledge of treatment of tuberculosis overseas, but further information can be obtained from Mr. E. M. BAVIN, Smith and Nephew Research Ltd., Gilston Park, Harlow, Essex.

King's College Hospital Medical School.—Inaugural address by Sir BASIL SPENCE, O.M., 29 September, 2.30 for 3 p.m., Medical School, Denmark Hill, London S.E.5.

King Edward's Hospital Fund for London.—Conference, "Estimating the Needs for Hospital Beds," 18 October, Hospital Centre, 24 Nutford Place, London W.1. Fee £1. Completed application forms by 6 October. This conference is the first of a series of three on making better use of hospital resources.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 11 September

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., Dr. M. E. A. Powell: Slide Seminar—Breast.●

Tuesday, 12 September

B.B.C. 2 TELEVISION.—1.15 p.m., medicine today: Fits (sponsored by A.S.M.E.).

KINGSTON-UPON-THAMES MEDICAL CENTRE.—1 p.m., Dr. W. E. Medd: "Sandwich" Seminar—Pulmonary Infarction (a tape recording).

ROYAL ARMY MEDICAL COLLEGE.—5 p.m., Mr. L. C. Oliver: Head Injuries.

WEXHAM PARK HOSPITAL, SLOUGH.—At Lecture Room, School of Nursing, 8.45 p.m., Mr. A. H. C. Ratcliff: Fractures of the Femoral Neck in Children.

Wednesday, 13 September

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting (buffet lunch).

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 2 p.m., Mr. S. Davidson: Diabetes in Pregnancy.●

ROYAL FREE HOSPITAL.—5.15 p.m., Dr. C. Merskey (New York): Thrombosis, Defibrination and Fibrinolysis.

Friday, 15 September

INSTITUTE OF DISEASES OF THE CHEST.—5 p.m., Dr. J. R. Bignall: clinical demonstration.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 3 p.m., Mr. D. M. Wallace: Cystoscopy and the Gynaecologist.●

Deaths

Laing.—On 27 August 1967, John Kidd Collier Laing, M.B., B.S., D.P.M., of 37 Heathclose Road, Dartford, Kent, aged 76.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.

Pointers

School Record Collated with Obstetrical History: Only five of the obstetrical complications considered by Drs. D. J. P. Barker and J. H. Edwards appeared to affect intellectual performance in 50,000 children studied in Birmingham, and impairment was slight. Multiple births were excluded (p. 695).

Importance of the Paraproteins: Dr. J. R. Hobbs finds that observing the level over years can aid in diagnosis of malignancy in doubtful cases (p. 699).

Lymphocytes in Hodgkin's Disease: Transformation response found to be low irrespective of therapy, but cells with anomalous chromosomes were attributable to radiation, and changes were not specific to Hodgkin's disease, according to Dr. Sylvia D. Lawler and colleagues (p. 704).

Hazard of Mushroom Cultivation: Dr. A. Sakula describes four patients with respiratory symptoms and miliary mottling on chest *x*-ray which cleared on removal from the environment (p. 708). Leader at p. 691.

Iron and Anaemia: Dr. R. H. Davis and colleagues found no relation between iron intake and haematological status in normal subjects, and concluded that iron loss is the determinant factor in haemoglobin levels (p. 711).

Acro-osteolysis: Raynaud's phenomenon and osteolysis of terminal phalanges reported in two workers dealing with polyvinyl chloride by Drs. D. K. Harris and W. G. F. Adams (p. 712).

Sickling and HbO: Two siblings showing both traits reported from the Sudan by Drs. S. A. Ibrahim and D. Mustafa (p. 715).

New Spirochaetosis: Drs. W. A. Harland and F. D. Lee describe 10 cases of spirochaetal infection of intestine (p. 718).

Weed-killer Death: Fatal poisoning from paraquat reported by Drs. Ch. Almog and E. Tal (p. 721). Leader, p. 690.

Further Case Reports: Volvulus of small intestine (p. 719). Trophoblastic activity as precipitating cause of pre-eclampsia (p. 720). Treatment of allergy to insulin (p. 722). Fragmentation of blood column in retinal vessels (p. 722). Avulsion of uterine fibroid (p. 723).

The Occasional Fit: Article supplementing television programme seen on 12 September and to be repeated on 19 September on B.B.C. 1. (p. 725).

Left-over Drugs: Dr. W. A. Nicholson reports on some 43,000 tablets collected from private houses (p. 730).

Legislation on Drugs: Summary of Government's White Paper (p. 734). Leader this page.

Vocational Training for General Practice: Summary of Advisory Committee's conclusions (*Supplement*, p. 129).

Control of Drugs

The great potency of many drugs now in common use has meant that against the benefit they offer must continually be weighed the risk they bear. Only last week the Dunlop Committee on Safety of Drugs drew attention to adverse reactions to psychotropic drugs (tranquillizers and antidepressants).[1] In the three years to June 1967, during which general practitioners had written 43,000,000 prescriptions for drugs in this group, the Committee had received over 1,200 reports of suspected adverse reactions to them, including 91 that were fatal. The Dunlop Committee itself came into existence on the recommendation of a joint subcommittee of the English and Scottish Standing Medical Advisory Committees set up after the thalidomide tragedy. And it has been the unanimous view of both the medical and pharmaceutical professions that it has carried out its task in exemplary fashion.

Now the Government's White Paper discussing forthcoming legislation on drugs and medicines[2] foreshadows substantial extensions of statutory measures to control their manufacture, import, quality, testing, and marketing. A brief summary of it is given at page 734. The Government proposes to set up a Medicines Commission. This body would advise the Ministers of Health and Agriculture on matters of policy, on the " pattern of expert committees " and their terms of reference, and on important technical points of principle in connexion with licensing, and it would be responsible for the preparation of the *British Pharmacopoeia* (instead of the General Medical Council). The Commission is to be " kept to a reasonable size," and its members will be appointed by the Minister after consultation with appropriate organizations. These would include the Royal Colleges, the G.M.C., the Medical Research Council, and the B.M.A., as well as bodies representing the veterinary surgeons and the pharmaceutical industry. A licence will be required for the marketing, importation, or manufacture of drugs, and for wholesale dealing in them, and the authority for licensing will rest with the Ministers of Health and Agriculture.

Nor does the Government intend to stop at controlling the manufacture and distribution of drugs, for the Ministers will also be empowered to make regulations controlling the advertising of them—to the general public, as at present, but in addition to professional audiences. " The content, format, and manner of presentation of advertisements for drugs " is to be within the scope of the proposed legislation, so that " those to whom the advertisement is directed are given adequate information about the drug."

In saying that the voluntary system, which is in operation at present, " has had the full support of the pharmaceutical industry and the medical and pharmaceutical professions " the White Paper is doing no more than endorse the annual reports issued by the Dunlop Committee and express the views of medical men and drug manufacturers. In fact the system has functioned exceedingly well, partly because the Committee, in addition to working with commendable efficiency, is an independent body that all

© *British Medical Journal*, 1967. All reproduction rights reserved.

concerned are confident to trust, partly because the absence of bureaucratic control has enabled advice and decisions to be given quickly, and, if necessary, informally. Why then does the Government now consider that statutory backing " would give greater reassurance and should not be further delayed " ? One reason advanced is that the Dunlop Committee itself has said it believed " the arrangements ought to be given permanence within the framework of legislation."[3] But it seems very questionable whether the Committee, in suggesting further statutory backing, had in mind anything like the all-pervasive Governmental control now proposed. A second reason for introducing the new legislation is that it is " believed to be broadly compatible with the arrangements " that will be laid down for the European Economic Community under the Treaty of Rome—that is, the Common Market. But, since other arrangements might be equally compatible, the ones set out in the White Paper should not be regarded as the last word in that respect.

That thorough checks on the manufacture and marketing of drugs are needed must be beyond dispute. At present they are satisfactorily exercised by the pharmaceutical industry in the course of research and manufacture, by the Dunlop Committee, and by the doctors who test and prescribe drugs. Despite the White Paper's expressed intention " to retain the flexible administration that has been so effective under the voluntary scheme," the ability of this or any Government to carry it out must arouse misgivings. Bureaucratic control rarely allows flexible administration. Nor is it clear how a system that vests in a Minister, a member of a political party, such complete control over the development and supply of drugs can command the confidence that the Dunlop Committee enjoys.

Some indication, perhaps no more, of the way the wind is blowing may be noted in the White Paper's remarks on the *British Pharmacopoeia*—to be taken over from the G.M.C. by the proposed Medicines Commission. " It is not intended," says the White Paper, " to prohibit the publication by other bodies of similar compendia . . . but as the scope of the compendia prepared under the aegis of the Commission widens, the scope of other compendia might diminish." The difficulty is to prevent much more than the scope of " compendia " from diminishing when control becomes centralized in Whitehall. The great danger is a deadening of the impulse to research that has revolutionized therapeutics in the last 30 years.

Poisoning from Paraquat

The question of differentiating " toxicity " from " hazard " is no more clearly illustrated than in the case of the herbicide paraquat (1,1′ dimethyl-4,4′-dipyridilium). In Great Britain there has been no death among people occupationally exposed to pesticides since 1953, and in each year fewer than 20 cases of poisoning are reported to the Ministry of Agriculture by their vigilant inspectors. These reported cases are mostly trivial—rashes or the effects of splashes in the eye—with one or two cases of systemic poisoning.[1]

The dipyridilium herbicides are a British invention, which could in some circumstances revolutionize agriculture by removing the need for the plough. The herbicides of this group act immediately on plants and are inactivated on coming into contact with soil. They are widely used for general control of weeds among plantation crops in Britain and overseas, and also for defoliation to facilitate harvesting of crops like cotton and potatoes. Workers applying these substances have sometimes suffered some nose bleeding owing to inhalation of spray droplets, but nothing more serious. The extraordinary activity of these compounds as weedkillers has led on several occasions to the illicit removal of concentrates from bulk and their diversion to private hands in small containers. When the container was a beer bottle two casualties resulted,[2] and other similar cases have been reported to the manufacturer.

At page 721 of the *B.M.J.* this week Drs. Ch. Almog and E. Tal record an unusual case of suicide by the subcutaneous injection of a 20% solution of paraquat. Animal experiments indicate that once absorbed into the body above a certain dose paraquat induces an irreversible disease process[3] despite the fact that over 90% is excreted within 24 hours.[4] The disease process—a cellular proliferation of the lungs—develops remorselessly and seems to represent a progressive chronic inflammation. Only paraquat does this. The pathogenesis of this lesion requires further study, and from work already published it is clear that the manufacturers of the herbicide are devoting considerable efforts to discovering more about its mode of action on the mammalian cell.

Meanwhile what sort of hazard does such a compound present ? Repeated small doses have no effect on laboratory animals, and repeated exposure seems to have no effect on agricultural workers, except that local irritation may occur after prolonged contamination of the skin. Yet the accidental ingestion of a single small quantity can provoke a fatal disease within two to three weeks. The only case known so far in which ingestion did not result in death is one in which a man swallowed the contents of the home garden pack of Weedol, containing 2.8 g. of paraquat formulated as granules.[5] Clearly a few drops from a watering-can containing this weedkiller are not likely to be dangerous to the suburban gardener. Nevertheless, the concentrate as issued to farmers and market gardeners can be very dangerous in a way that may mislead doctors owing to the delay in the onset of its effects. In a recent case (unreported) a child drank from a Coca Cola bottle in which its parent had put some paraquat illicitly obtained from a market garden. The child appeared to recover from the acute effects, was sent home, but died two weeks later.

Many modern herbicides have a very low acute toxicity to man. The immediate effects of paraquat are mild, but fatal poisoning may be delayed in onset. In any case of suspected suicide or accidental poisoning from swallowing of a weed-killer the doctor would be well advised to make certain that the preparation was not a dipyridyl type of herbicide before assuming that an early recovery from poisoning will be permanent. A sample of urine should be analysed as soon as possible, and if this shows that the patient has absorbed any significant amount of paraquat he should be treated, in the absence of any known specific measures, on general principles. These would include stomach wash-out and the promotion of diuresis by mannitol. If there are signs of renal failure, dialysis should be considered. Unfortunately no treatment has yet been found effective once the lung lesions develop.

Allergic Alveolitis

Mushroom-worker's lung, like bird-fancier's lung,[1] is one of a group of pulmonary allergic diseases due to inhaled organic dusts, for which the term "extrinsic allergic alveolitis" has been suggested. Farmer's lung is the classical example.

The inhalation of organic dusts may cause two main forms of allergic disease, affecting either the bronchi, with the production of asthma, or the peripheral lung tissues, with the production of a mainly alveolar reaction. An analysis[2] of the factors which determine these important differences shows that atopic persons give bronchial asthmatic reactions which are mediated by non-precipitating, reaginic antibody (type I allergy[3]), whereas non-atopic persons give predominantly alveolar reactions, provided the dust particles are small enough to penetrate to the alveoli. These reactions are mediated by precipitating antibody (type III allergy[3]).

Many organic dusts cause allergic alveolitis. The diseases include farmer's lung,[4] bagassosis,[5] maple-bark disease due to the fungus *Cryptostroma corticale*,[6] lung disease due to the grain weevil *Sitophilus granarius*,[7] bird-fancier's lung due to avian antigens,[8] and pituitary snuff-taker's lung due to porcine and bovine posterior pituitary powder.[9] In the *B.M.J.* this week (page 708) Dr. Alex Sakula adds another—namely, mushroom-worker's lung, due to actinomycetes that flourish in hot, damp vegetable matter. In all of these diseases precipitins have been found in the serum against the relevant antigens. Other similar diseases in which precipitins have either not yet been found or not certainly identified include suberosis due to cork dust, paprika-splitter's lung, smallpox-handler's lung,[10] and the chronic lung disease of New Guinea natives attributed to dust from thatched roofs.[11]

Extrinsic allergic alveolitis, whatever its cause, has a common pattern of clinical symptoms, all of them present in the patients suffering from mushroom-worker's lung. They are entirely different from the wheezing of the asthmatic patient, in whom pulmonary function tests show airways obstruction. Systemic reactions are an important feature of allergic alveolitis, and may consist of fever, chills, and malaise, with aches and pains, followed by a marked loss of weight. The pulmonary symptoms and signs are those of a chiefly alveolar reaction. They consist of cough, and of dyspnoea, which is often severe and out of proportion to the paucity of the crepitant rales which may be heard. Tests of pulmonary function show a restrictive defect, with impairment of gas transfer and decrease in lung compliance, with little, if any, evidence of airways obstruction.[4, 12, 13] Such tests are now becoming an essential part of the investigation of patients with lung disease.

Radiographic examination in the early stages usually shows nodular shadows, frequently micronodular, and of a wide distribution, as might be expected from the inhalation of large amounts of finely particulate dust capable of reaching the alveoli. In the late stages there is radiographic evidence suggestive of fibrosis, with diffuse honeycomb changes, affecting particularly the upper lobes.

Histological examination of the lungs shows, in the early stages, infiltration of the alveolar walls with polymorphonuclear, lymphoid, and plasma cells, and in the later stages epithelioid-cell granulomata and fibrosis are present. In about one-quarter of patients with farmer's lung bronchiolitis obliterans was also found.[14]

The disease may present in two ways.[4, 8] The classical form consists of systemic and pulmonary symptoms appearing five to six hours or more after exposure to the dust. Such attacks may subside rapidly, only to recur on re-exposure. The disease may also have an insidious onset and is then, if anything, the more dangerous, because the relationship of the symptoms to the causal exposure is far less likely to be suspected. The gradual development of the disease results in the patient's seeking medical attention when fibrosis is far advanced and irreversible. The differences in the mode of onset appear to be related to the frequency and intensity of exposure to the dust. Inhalation tests in both groups of patients provoke the same classical attacks of the disease, coming on after five to six hours or so.[8]

Management of the disease must be based on avoidance of the antigens. This makes it imperative that inhaled dusts should be considered as possible causes in patients with disease affecting the alveoli or with pulmonary fibrosis. Fortunately, the precipitin test offers a means of identifying the antigen, though the presence of precipitins can be taken in the first place only as evidence of exposure to the antigens. Inhalation tests help to confirm the cause by reproducing the disease, and when a new dust is recognized such tests are needed to establish the clinical relevance of the immunological findings. Once the significance of the serological tests has been established, inhalation tests may reasonably be omitted. Farmers can avoid exposure to thermophilic actinomycetes by keeping down the moisture content of the hay.[15] Mushroom workers face greater difficulties, because in the making of their compost many actinomycete spores are inevitably produced.[16] Masks are of limited value, because of the very small size of the spores of the thermophilic actinomycetes—only about 1 μ in diameter.[17]

While in farmers and mushroom workers antigens from micro-organisms are the cause of the allergic alveolitis, it is worth noting that organic dusts from any source are possible causes of similar serious disease. There is evidence that precipitins are commonly present in persons exposed to a wide range of vegetable dusts.[18]

Doctors for Industry

There are about 2,000 appointed factory doctors in Britain, most of whom are general practitioners. They examine young persons entering industry, advise both the employer and the employee in cases where a disease or disability is likely to be affected by working conditions, and have various other statutory duties. Last year a Ministry of Labour report[1, 2] recommended that these part-time factory doctors should be replaced by a much smaller group of 100 " A doctors," still responsible to the Ministry of Labour.

The report has been the subject of much controversy, both among doctors in industry[3, 4] and elsewhere, and the Industrial Health Committee of the Royal College of Physicians[5] has now commented on it. The Royal College report agrees " that the present Appointed Factory Doctor Service does not meet the needs of the working population," but goes on to point out that the envisaged 100 A doctors will serve only that part of the working population covered by the Factories Acts, whereas those covered by the Shops, Offices and Railway Premises Act will be left out, as will many other groups of workers, such as fishermen.

The Royal College report suggests that as the A doctors' role would be mainly to give advice they should answer to the Ministry of Health and not the Ministry of Labour. As well as emphasizing the advisory function of A doctors this would improve their career structure and facilitate their recruitment from the National Health Service, especially as they might be part-time in the first instance. A doctor could have secretarial assistance and trained ancillary services provided by the N.H.S. for carrying out radiological, physiological, and haematological investigations. The Royal College report suggests that an industrial hygiene service could be organized by regions, preferably based on the universities.

The most contentious proposal in the original report from the Ministry of Labour was that school doctors should issue all school-leavers with a standard certificate, which would make the examination at entry to industry unnecessary. The Royal College Committee agreed that the numerous young persons' statutory annual examinations at present carried out by the appointed factory doctors are largely a waste of time and took the view that the pre-employment medical certificate was a satisfactory substitute.

However, the B.M.A. Occupational Health Committee is far less happy with the idea of the certificate and has made its views known to the Minister of Labour. At any pre-employment examination of a young person by an industrial medical officer or an appointed factory doctor, not only is the employer already chosen but the actual job that the school-leaver is going to do is known to the examiner. If the School Medical Service issues a certificate of fitness for most leavers and a small group receives a " disabled " certificate it may lead to the employer deciding which jobs are " heavy " or have a " high dermatitis hazard," and may also make it easy for an unscrupulous employer to refuse all but the healthy school-leavers. This is an interference with the individual's freedom to apply for any sort of occupation which he himself chooses, and another step in the creation of a State dossier on each citizen. This restriction is to be foisted on school-leavers as part of an inescapable administrative scheme, and is based only on the evidence of a school doctor at the beginning of this person's working career. The doctor may err, or the patient's condition may improve.

The solution put forward by the B.M.A. is that a handbook should be issued for the guidance of school medical officers, listing the medical handicaps which might be hazardous for school-leavers in open industry. Young persons with these disabilities could be referred to the A doctor for his advice. He could then take the matter up with the general practitioner and the youth employment officer and eventually with the proposed employer.

The Association of Certifying Factory Surgeons, which is the recognized body of the appointed factory doctors, has not yet committed itself to print but seems to be viewing its members' demise with equanimity, while at the same time regretting that all the emphasis has been placed on the time-wasting statutory examinations of young persons and that no mention has been made of the valuable service that appointed factory doctors have already carried out in the field of occupational health.

However, the climate of expert opinion appears to favour the appointment of A doctors, if they will become occupational health advisers under the Ministry of Health serving on area health boards as envisaged by the Porritt Committee.[6] These men could then become the basis of a national occupational health service, a service which the Treaty of Rome demands in a field where Britain lags behind most other civilized countries.

Treatment of Addicts

The Dangerous Drugs Bill was introduced to " provide for the control of drug addiction." Moving the second reading in April, Miss Alice Bacon[1] claimed that the Bill paved the way for a major change in the organization of treatment for addicts. Fundamental to that change was the establishment of treatment centres in hospitals. However, until there are enough of these centres to cope with the number of cases there is no possibility of getting away from the existing practice of individual doctors prescribing heroin and other drugs as they see fit.

Government spokesmen have repeatedly stated that plans for the provision of these centres are proceeding smoothly, and that they hoped that the regulations limiting prescription of drugs to addicts would be introduced in 1968. But the Ministry of Health has refused[2] to provide hospital boards with the money for treatment centres, and there is little evidence that they are being established. The Ministry refuses to name the hospitals where the centres are to be or to give any details of their progress. The existing outpatient facilities for addicts in the London area are certainly inadequate to meet the demand that will be created when the regulations forbidding private prescribing come into operation.

Recent discussion[3] [4] in the *B.M.J.* of British and American experience has made it clear that the best treatment for addicts is not yet agreed. If the Government really means to tackle the growing problem of drug addiction it must make money available to equip and staff treatment centres, which could then be used to assess the merits of different ways of treatment—the use of differing degrees of compulsion, the value of drugs such as methadone and cyclazocine, and the use of community-centred programmes. The profession has been assured[2] that the new regulations will not be brought into operation until there are adequate centres. It is equally important for the Government to show some practical evidence of its professed sense of the urgency of the problem by providing the money needed to cope with it.

Australian Doctors in Vietnam

The pressing needs of the civilian population in Vietnam for the benefits of modern medicine are apparent from a recent Australian study. A symposium on the work of Australian surgical teams there, reported in full in the *Medical Journal of Australia*,[1] provides a story which is both tragic and inspiring. It is tragic because of the amount of human suffering concentrated in Vietnam ; inspiring because of the help which these teams are bringing to that country.

Two problems in particular stand out: a primitive existing medical service which can provide only the most sketchy facilities—so that the disease picture is nineteenth-century or earlier—coupled with a large number of civilian casualties produced by all the refinements of modern warfare from napalm-charring to the multiple wounds of Claymore mines.

The bare outlines of the medical situation in South Vietnam are as follows. There is a population of about 15 million people, of which about 10% are refugees. The average life-expectancy is 38 years, and about one-quarter of infants born alive are dead before the age of 5. Causes of death include tuberculosis, pneumonia, malaria, typhoid fever, and the dysenteries. Other major diseases include cholera, plague, leprosy, and worm infestations. In December 1965 there were only 244 doctors available for the civilian population (180 of these were Vietnamese and 64 from other countries). The present proportion of doctors to population is 1 to 61,000.

Australia's assistance with financial non-military medical aid is second only to that of the U.S.A., and in addition since 1964 she has sent from Melbourne surgical and medical teams totalling 75 doctors together with nurses and technicians who work a three- to six-month tour of duty. At present there are 28 teams in South Vietnam from 13 countries, of which Australia provides three. Only three other countries provide more than one team, and these are Korea (7), the Philippines (5), and the U.S.A. (4). The United Kingdom has one paediatric unit at present serving in Vietnam.

The bare statistics provided by P. G. Large in this symposium give some idea of the amount of work to be done. In 15 months the Australian teams carried out over 4,000 operations, a total of 270 cases per month, of which three-quarters were major. About half the cases were emergencies, of which two-thirds were traumatic in origin. Individual case histories help fill in the background to these figures—children injured playing with a grenade, an amputation case arriving two days later with artery forceps still attached to the stump of the leg, a woman with a bullet wound involving the common carotid artery who travelled 36 hours and 100 miles (160 km.) to reach the hospital, and patients arriving with their wounds stuffed with tobacco.

The report from the plastic surgeon, John Snell, shows that there are only two civilian plastic surgeons in the whole of Vietnam, neither specially trained. Three Australian plastic surgeons have battled with the vast array of advanced deformity. The tasks of the nurses are also immense, as reported by Miss Susan Terry ; in provincial hospitals there may be three nurses to tend 500 patients.

Summing up the symposium, J. D. Villiers gives the three aims of these Australian teams: firstly, humanitarian, the care of civilian sick and wounded ; secondly, diplomatic, in that the teams are tangible evidence of Australia's concern for her less fortunate neighbours in South-east Asia ; and, thirdly, the training of Vietnamese personnel. A primary function of the team is to leave behind it a structure capable of continuing its work.

Disc Protrusion and the Bladder

It is well known that lesions of the lower spinal cord and the cauda equina may interfere with neurological control of the bladder. Congenital defects, trauma, pressure from neoplasms, and inflammatory conditions are responsible for most of the cases. The role of lumbar disc protrusions is less clearly defined, and a diagnosis of bladder dysfunction from this cause when the characteristic features of local muscular spasm and referred pain are absent might at first sight appear questionable.

In a recent report from the Mayo Clinic J. G. Love and J. L. Emmett[1] described three cases in which urinary retention was attributed to asymptomatic lumbar disc protrusions and in which normal function was restored by appropriate surgery. All the patients were women and somewhat fat. All had suffered from enuresis in childhood, but no other neurological factor had been suspected and neither physical examination nor myelography had shown any abnormality. At cystoscopy there was a large vesical residue, but suspicion was aroused by the absence of sensation on instrumentation and the lack of discomfort on further distension of the bladder. In each case the bladder was smooth and could expel urine normally through the cystoscope. Laminectomy was done to explore the filum terminale and in each case it revealed a protruded lumbar disc which proved to be the cause of the symptoms.

It is worth noting that all the patients were women. Urinary retention is relatively uncommon in women, except when due to gynaecological causes or cystitis, and it is prone to be ascribed to "hysteria." Clinical experience indeed suggests that in many instances the condition is transient and is permanently relieved by simple catheterization. But there are none the less some patients in whom dysfunction persists despite elimination of any urinary infection and treatment with cholinergic drugs. The usual management of these cases has been to carry out a limited perurethral resection of the bladder neck to relieve a hypothetical obstruction. It seems surgeons should now first investigate the termination of the spinal cord in more detail in such resistant cases.

Hypotonia and Obesity Syndrome

Lack of muscle tone in the newborn infant is a common problem. Usually there is a history of foetal distress, followed by the delivery of an apnoeic hypotonic infant requiring resuscitation. During the ensuing weeks or months it becomes clear whether any permanent cerebral damage has occurred.

A difficult delivery, not necessarily a breech, with excessive traction on the neck may damage the spinal cord, usually in the lower cervical region, causing initially a flaccid paralysis of trunk and legs. Occasionally a widespread poliomyelitis may develop in utero as a result of a maternal infection during pregnancy; or there may be a transient myasthenic phase in an infant whose mother has myasthenia gravis. If a previous child was severely hypotonic at birth and died at an early age the possibility of the infantile form of degeneration of the anterior horn cells of the spinal cord (Werdnig–Hoffmann disease) should be considered. Less commonly the picture may merely mimic disease of the anterior horn cells, but there is a gradual improvement, though this is not always complete. This is the condition or group of conditions known as "benign infantile hypotonia"; a familial incidence is uncommon. Marked weakness of sucking, with a bilateral convergent squint, usually indicates a form of Möbius's syndrome, with agenesis of the motor nuclei of the sixth and seventh (and occasionally other) cranial nerves.

There remains a small group of infants with extreme hypotonia from birth, an almost complete lack of spontaneous movement, and an inability to suck. B. M. Laurance[1] has recently surveyed the literature, and has reported nine cases of his own, describing a condition which begins in this way but evolves in a curious manner. In the males the external genitalia are very small and the testes are small or impalpable. As these infants get older muscle power improves, but they remain hypotonic, and it soon becomes apparent that their delayed motor development is due partly to muscle weakness and partly to mental retardation. By the age of 4 to 5 years they are usually dwarfed and extremely fat, and from the age of 12 years onwards they tend to develop diabetes. This syndrome was first described from Zürich by A. Prader, A. Labhart, and H. Willi[2] in 1956. Other reports from Sweden,[3] England,[4] and Belgium[5] suggest that it is not uncommon.

In most of the families studied so far there has been no indication of a genetic basis, though J. C. Gabilan[6] found two affected children in one family. Nor has any significant environmental factor been discovered. Systematic investigation has not been of much help. It has been observed that the majority of the affected children have a similar facial appearance, with "almond-shaped eye sockets with slightly overhanging lids, a high cranial vault above the ears when seen in profile, prominent foreheads, retroussé noses, and slightly open fish-like mouths"[1]; the hands and feet are small and narrow. The possibility of a chromosomal abnormality has been considered, particularly as the angle between the palmar triradii is the same in some cases as that found in Down's syndrome (mongolism). H. G. Dunn and his colleagues[7] reported a minor chromosomal abnormality in one case, but the significance of this finding is uncertain, as neither Laurance[1] nor H. Forssman and B. Hagberg[3] found any such abnormalities in their cases. Electroencephalography has shown no constant abnormality, nor has electromyography. Muscle biopsies were done in two of Laurance's cases: in one the appearance was normal and in the other Dr. A. L. Woolf suggested there was a "dysplasia of the lower motor neurones" or an "actively progressive degeneration." Glycogen content and muscle enzymes have been shown to be normal in another case. In one patient a biopsy of the testis showed an appearance consistent with the age of the child, who was prepubertal.

Investigations of the function of the pituitary and adrenal cortex have given normal results in most cases, but in Forssman and Hagberg's case there was a reduced response to A.C.T.H. The diabetes which develops in these children appears to be less acute than is usually seen in children, and ketosis is often absent. These observations led P. R. Evans[4] to suggest that an insulin antagonist[8] might be present, interfering with the uptake of glucose by skeletal muscle but enhancing its uptake by adipose tissue.

It is not clear whether the small external genitalia and testes (and presumably ovaries) are an expression of primary or secondary hypogonadism. Puberty is delayed and incomplete, and in one of the Swiss cases[2] the excretion of gonadotrophin was abnormally high, suggesting a primary gonadal deficiency. If there is a persisting hypogonadal state, either primary or secondary, production of growth hormone may also be deficient, as a eunuchoid state does not develop. There is still much that is obscure in this interesting syndrome, and it remains to be seen whether there is a single basic abnormality or whether the syndrome comprises several different but similar conditions.

Guide to Hospitals

Following the example of Baedeker, many diligent guides have set out to help the newcomer find his way round with pleasure and enlightenment. Culture and sport, eating and sleeping—these and other human aspirations and frailties are the subject of many an instructive handbook. One of special interest to doctors seeking hospital junior appointments is *The Hospital Gazetteer*, published by the British Medical Association.[1] It contains a mass of information about the hospitals of Great Britain, Northern Ireland, and the Isle of Man. The traveller in this bewildering world is given pithy guidance on the sort of reception and accommodation he may expect. For example, one hospital has "Catering very high standard; good facilities for meals at night." Another offers accommodation "above the minimum laid down" but "off-duty time inadequate." Some further samples are: "28 rooms too small, 24 have no wash-basins." "Social club with old-time and modern dancing, drama section, archery, photography." "H.P.s' sitting-room is used as dining-room by resident medical staff and visiting consultants." "Rooms have no desks, easy chairs, nor running water." Thus with the help of this book the young doctor seeking decent accommodation in which to live, work, and study should be able to pick out a congenial billet and keep clear of "accommodation inadequate."

Obstetric Complications and School Performance

D. J. P. BARKER,*† M.B., B.SC., PH.D.; J. H. EDWARDS,* M.R.C.P.

Brit. med. J., 1967, **3**, 695–699

Little is known about the mental development of children who are exposed to obstetric complications and escape the immediate hazards of perinatal death or severe brain injury. This lack of knowledge results from the practical difficulties involved in collecting the obstetric histories of a large number of infants and relating them to school performance, or to some other index of intellectual development, several years later. During the past 16 years obstetric records have been compiled for all births within the City of Birmingham, and these now permit an analysis of the relation between obstetric history and performance in the verbal reasoning tests which form part of the selective examination for 11-year-old schoolchildren.

Since performance in verbal reasoning tests is determined by genetic endowment, prenatal environment, and the physical and social environment after birth, data relating small differences in performance to obstetric events can be interpreted only against a control population matched for similar hereditary, prenatal, and postnatal determinants. Therefore unless the differences are large sibs provide the only possible controls.

In this paper the verbal reasoning scores of children exposed to obstetric complications are compared with those of their sibs and of the population of 50,000 children to which they belong.

Method

The population comprised all children who were born in Birmingham during 1950–4 and subsequently took the "eleven-plus" examination there. It did not include children who left the city or died before the age of 11 years, or who did not take the examination because they were in private schools, special schools for the handicapped, or, though in ordinary schools, had been assessed as "borderline subnormal."

Eleven-plus candidates have to take two verbal reasoning tests. These are a form of group intelligence test, and the means of the two scores obtained are transformed and adjusted so that the scores of candidates born in different months have a mean of 100 and a standard deviation of 15. The present investigation is based on analysis of these age-adjusted verbal reasoning (V.R.) scores.

Obstetric data which have been recorded on punch cards for all births in Birmingham since 1950 (Charles, 1951) were converted into a constant format and transferred to magnetic tape. The eleven-plus results of all children who took the examination in Birmingham during 1961–5 were made available, and these also were transferred to magnetic tape. The records on the two data tapes were sorted into sequence depending on names and dates of birth, and the data were merged to form a third tape. An eleven-plus record was linked with a birth record if the first name, surname, and date of birth were identical when expressed in the Hogben numeric code (Hogben, Johnstone, and Cross, 1948). As a result of this procedure birth and examination records of 50,046 children were linked.

Children born during the last quarter of 1954 were too young to have taken the eleven-plus during 1965, and the population of 50,046 children was therefore restricted to those born from 1 January 1950 to 1 September 1954. Subsequent comparison of surnames and addresses on the combined birth and eleven-plus records led to identification of 12,959 sibs from 6,129 fraternities within the population.

Results

Plurality

Table I shows that the mean V.R. scores of twins and triplets are 4.8 and 13.3 units below the mean score of single-born children. This confirms the observations of Mehrotra and Maxwell (1949) and of Sandon (1957). As multiple pregnancies impose a peculiar prenatal environment, and the survivors have an unusual upbringing, further analysis in this paper is restricted to the 48,795 single-born children.

TABLE I.—*Mean V.R. Scores According to Plurality*

Single-born	Twins	Triplets
100·2 (48,795)	95·4 (1,233)	86·9 (18)

Numbers of children are given in parentheses.

Birth Rank

The number of previous livebirths and stillbirths was recorded for all except 50 of the children. Within the population the mean V.R. score falls with increasing birth rank, from 102.8 in birth rank 1 to 89.3 in birth ranks 10 or more (Table II). Comparison of mean scores of sibs in each birth rank with those of sibs in the preceding rank (Table III) shows that within fraternities the V.R. score falls with increasing birth order, with an average fall of 1.0 for each unit increase in birth order.

Duration of Gestation

The gestation period, calculated to the nearest week from the first day of the last menstrual period, was recorded for

TABLE II.—*Mean V.R. Scores According to Birth Rank*

Birth Rank									
1	2	3	4	5	6	7	8	9	10+
102·8 (17,065)	101·6 (13,803)	98·8 (8,122)	96·6 (4,378)	93·8 (2,296)	93·1 (1,303)	92·4 (748)	90·4 (439)	89·8 (270)	89·3 (321)

† Present address: Department of Medicine, Medical School, The University, Birmingham 15.

Table III.—*Mean V.R. Scores in Sib Pairs According to Birth Rank*

	Birth Rank									Total
	1	2	3	4	5	6	7	8	9	
Children in each birth rank (a)	—	100·2	98·1	95·7	93·2	91·5	93·1	91·0	90·3	97·7
Children in preceding birth rank (b)	—	101·7	99·1	96·0	94·1	92·4	92·0	91·4	88·8	98·7
Difference (a)–(b)	—	−1·5 (2,208)	−1·0 (1,293)	−0·3 (711)	−0·9 (413)	−0·9 (211)	+1·1 (126)	−0·4 (74)	+1·5 (49)	−1·0 (5,085)

41,452 children (85%). The mean V.R. scores of children born at term (38 to 41 weeks) are above average; but the children born after either longer or shorter gestations have mean scores below the average (Table IV). Table V shows the mean scores among pairs of sibs in consecutive birth ranks, of whom one member was born at term (term sib) and the other was born either before term (28 to 37 weeks) or after term (more than 41 weeks). Because of the relation between V.R. score and birth order within fraternities (Table III) the results are subdivided according to whether the term sib is the earlier- or later-born member of the pair. In the sib pairs which include one child born before term both sibs were born after pregnancies uncomplicated by antenatal disease and after labours of spontaneous onset. In the pairs in which one child was born after term both sibs were likewise born after uncomplicated pregnancies but sibs born after induced labours were not excluded.

Table IV.—*Mean V.R. Scores According to Duration of Gestation in Fortnights*

28–	30–	32–	34–	36–	38–	40–	42–	44+
80·1 (15)	95·8 (89)	93·5 (186)	96·3 (635)	97·4 (2,170)	100·3 (10,169)	100·7 (22,410)	99·4 (5,119)	97·1 (659)

In Table V the mean scores of affected children—that is, of sibs born before and after term—exceed those of their term sibs in the subsequent birth rank by 1.2 and 0.7 respectively. This may be attributed to the higher birth order of the term sibs. But when affected children are compared with term sibs in the preceding birth rank their mean scores are 2.5 and 1.8 lower. These differences exceed the average fall of 1.0 for each unit increase in birth order and, together with the lower mean scores in the population (Table IV), they suggest that shortened and prolonged gestation periods are associated with impaired performance on V.R. tests. There is, however, no marked difference in the percentage distribution of scores of children born before, at, or after term (Table VI).

Table V.—*Mean V.R. Scores in Sib Pairs of Whom One Member Was Born at Term (38 to 41 Weeks of Gestation) and the Other Either Before Term (28 to 37 Weeks) or After Term (More Than 41 Weeks)*

	Born Before Term	Born After Term
Affected children (a)	97·6	96·7
Sibs in subsequent birth rank born at term (b)	96·4	96·0
Difference (a)–(b)	+1·2 (120)	+0·7 (229)
Affected children (c)	95·0	96·9
Sibs in preceding birth rank born at term (d)	97·5	98·7
Difference (c)–(d)	−2·5 (163)	−1·8 (312)

Numbers of sib pairs are given in parentheses.

Antenatal Diseases

The presence or absence of antenatal disease was recorded for 45,650 children (94%), and Table VII shows the mean V.R. scores of children born after pregnancies complicated by toxaemia, non-toxic antepartum haemorrhage, or anaemia.

Table VII.—*Mean V.R. Scores According to Antenatal Disease*

Toxaemia	Non-toxic A.P.H.	Anaemia
101·9 (3,321)	97·9 (641)	97·4 (1,338)

In the compilation of the birth records the coding "toxaemia" was applied to all cases of hypertension or albuminuria during pregnancy. The mean V.R. score of children born after toxaemic pregnancies is above the population mean. But the incidence of toxaemia in birth rank 1 is twice that in the other ranks; and children in birth rank 1 have the highest mean V.R. scores (Table II). When children from toxaemic pregnancies are distributed according to birth rank, their mean V.R. score is consistently greater than the mean for all children in the same birth rank (Table VIII). Since, however, less intelligent mothers tend to neglect regular antenatal examination, there is probably a correlation between maternal intelligence and the diagnosis of toxaemia; and the intellectual performance of mothers and their children is known to be correlated.

Table VIII.—*Mean V.R. Scores of Children Affected by Toxaemia, According to Birth Rank*

	1	2	3	4	5	6+
Children affected by toxaemia	103·7 (1,855)	101·9 (725)	100·1 (325)	96·7 (186)	94·7 (93)	92·2 (136)
Whole population of children	102·8	101·6	98·8	96·6	93·8	91·9

Table IX, constructed in the same way as Table V, shows that the mean V.R. score of children from toxaemic pregnancies is only 0.5 above that of their sibs in the subsequent birth rank and is 2.0 below that of sibs in the preceding rank. This suggests that toxaemia is associated with an impaired V.R. test performance. Table X shows that in sib pairs, of which both members were born at term (38 to 41 weeks of gestation), children from toxaemic pregnancies were at a great disadvantage compared with their normal sibs. The association between toxaemia and impaired V.R. performance does not therefore seem to be secondary to the known association between toxaemia and a shortened period of gestation. In accord with their higher mean score the distribution of scores of children from toxaemic pregnancies differs slightly from that of the whole population of children (Table XI).

The mean V.R. score of children affected by non-toxic antepartum haemorrhage is 97.9 (Table VII). This may be compared with a mean score of 99.5 for children with the same

Table VI.—*Percentage Distribution of V.R. Scores According to Duration of Gestation*

Duration of Gestation	V.R. Score								No. of Children	Mean Score
	Below 70	70–	80–	90–	100–	110–	120–	130+		
28–37 weeks	3·5	8·4	18·4	26·4	25·1	13·0	4·5	0·9	3,095	96·8
38–41 "	1·6	5·8	14·7	25·1	25·7	17·6	7·5	2·0	32,579	100·6
42+ "	2·1	6·8	16·2	26·2	24·7	16·5	6·1	1·4	5,778	99·1

birth-rank distribution. However, the scores of affected children are not lower than those of their unaffected sibs (Table IX). "Non-toxic antepartum haemorrhage" is a description that was applied to antepartum bleeding which resulted from many causes but was not associated with toxaemia; and even some cases of threatened abortion were classified in this way. From the results in Tables VII and IX one can draw only the general conclusion that disturbances of the placenta which result in bleeding during pregnancy, in the absence of toxaemia, do not usually influence subsequent V.R. performance.

TABLE IX.—*Mean V.R. Scores in Sib Pairs According to Antenatal Disease*

	Toxaemia	Non-toxic A.P.H.	Anaemia
Affected children (a)	100·3	99·8	97·7
Unaffected sibs in subsequent birth rank (b)..	99·8	98·1	95·3
Difference (a)–(b)	+0·5 (180)	+1·7 (44)	+2·4 (92)
Affected children (c)	100·8	95·1	97·9
Unaffected sibs in preceding birth rank (d)..	102·8	94·5	98·7
Difference (c)–(d)	−2·0 (162)	+0·6 (66)	−0·8 (191)

TABLE X.—*Mean V.R. Scores in Sib Pairs Both of Whom Were Born at 38–41 Weeks of Gestation and One of Whom Was Affected by Toxaemia or by Non-haemolytic Jaundice*

	Toxaemia	Non-haemolytic Jaundice
Affected children (a)	100·8	102·0
Unaffected sibs in subsequent birth rank (b)	101·5	101·6
Difference (a)–(b)	−0·7 (87)	+0·4 (36)
Affected children (c)	101·0	104·7
Unaffected sibs in preceding birth rank (d)	103·2	105·0
Difference (c)–(d)	−2·2 (100)	−0·3 (42)

All types of anaemia were grouped together as "anaemia." The lowered mean V.R. score of children affected by anaemia (Table VII) may be partly or wholly the result of the known association between anaemia of pregnancy and poor social circumstances. There is no evidence that the V.R. performance of affected children differs from that of their unaffected sibs (Table IX).

Presentation at Onset of Labour

Table XII shows the mean V.R. scores of the 45,291 children (93%) whose type of presentation was recorded. Although the mean score of all children whose presentation was occipito-posterior is 100.4, the mean score of affected sibs is only 0.1 above that of unaffected sibs in the subsequent birth rank and is 2.5 below that of unaffected sibs in the preceding rank (Table XIII). This is evidence of an association between occipito-posterior presentation and an impaired V.R. performance. The percentage distribution of the affected children is similar to that of the whole population of children (Table XI).

In Tables XII and XIII there is no evidence of any marked association between other forms of presentation and V.R. performance, though the numbers of brow presentations and presentations caused by a transverse lie were too small to permit comparisons within sib pairs.

TABLE XII.—*Mean V.R. Scores According to Type of Presentation at Onset of Labour*

Normal Vertex	Occipito-posterior	Brow	Face	Breech	Caused by Transverse Lie
99·8 (41,929)	100·4 (2,232)	106·9 (35)	98·5 (116)	99·2 (913)	99·5 (66)

TABLE XIII.—*Mean V.R. Scores in Sib Pairs According to Type of Presentation at Onset of Labour*

	Occipito-posterior	Face	Breech
Affected children (a)	97·8	100·2	102·3
Unaffected sibs in subsequent birth rank (b)..	97·7	89·4	99·1
Difference (a)–(b)	+0·1 (188)	+10·8 (9)	+3·2 (56)
Affected children (c)	96·9	92·1	95·1
Unaffected sibs in preceding birth rank (d)..	99·4	93·2	97·6
Difference (c)–(d)	−2·5 (229)	−1·1 (12)	−2·5 (96)

Type of Labour

In the records of 46,236 (95%) of the children the type of labour was classified to show whether the onset was spontaneous or induced, and whether delivery was natural, instrumental, or by caesarean section.

The mean V.R. score of children born by instrumental delivery is 103.5 (±0.4) (Table XIV). This may be compared with a mean score of 102.0 for children with the same birth-rank distribution. The mean score of 103.0 (±0.5) for children born by caesarean section may be similarly compared with a mean score of 101.2. Within fraternities the mean score of children born by instrumental delivery is higher than that of sibs in both the subsequent and preceding birth ranks (Table XV). Though small numbers make interpretation difficult, Table XV also suggests that the V.R. performance of children born by caesarean section is better than that of their sibs.

TABLE XIV.—*Mean V.R. Scores According to Method of Delivery*

Natural	Instrumental	Caesarean Section	"Other"
99·6 (43,452)	103·5 (1,661)	103·0 (1,016)	101·7 (107)

TABLE XV.—*Mean V.R. Scores in Sib Pairs According to Method of Delivery*

	Instrumental	Caesarean Section
Affected children (a)	102·3	106·6
Unaffected sibs in subsequent birth rank (b)	100·0	96·5
Difference (a)–(b)	+2·3 (145)	+10·1 (9)
Affected children (c)	97·1	95·9
Unaffected sibs in preceding birth rank (d)	95·5	93·2
Difference (c)–(d)	+1·6 (34)	+2·7 (13)

TABLE XI.—*Percentage Distribution of V.R. Scores of Children Affected by Toxaemia, Occipito-posterior Presentation, or Delivery in an Ambulance*

	V.R. Score								No. of Children	Mean Score
	Below 70	70–	80–	90–	100–	110–	120–	130+		
Toxaemia	1·6	4·7	12·7	24·7	26·5	18·8	8·3	2·6	3,321	101·9
Occipito-posterior presentation	1·6	5·5	14·9	25·6	25·7	18·3	6·6	1·8	2,232	100·4
Delivery in an ambulance	5·2	9·2	20·4	31·2	18·8	10·0	4·8	0·4	250	94·3
Whole population of children	1·8	6·3	15·3	25·0	25·3	17·2	7·3	2·0	48,795	100·2

In the classification of type of labour the category "other" denoted labours and deliveries which were regarded as unusual. This category was not strictly defined, but its most frequent use was for labours which ended in breech extractions. The mean V.R. score of children born after "other" types of labour is 101.7 (Table XIV) and therefore exceeds that of the whole population. Numbers were too small to permit comparisons within sib pairs.

Precipitate Labour

In the compilation of the birth data a simple classification was used to denote the duration of labour. The time recorded was that from the beginning of the first stage until the completion of the second. For children born after labours completed in two hours or less (a precipitate labour) the mean V.R. score is 97.7 (Table XVI). This may be compared with a mean of 99.0 for children with the same birth-rank distribution. Although the mean score of affected children is 2.5 above that of sibs in the subsequent birth rank and only 0.5 below that in the preceding rank (Table XVII), these differences seem too small to justify the conclusion that precipitate labour and V.R. performance are associated.

TABLE XVI.—*Mean V.R. Scores of Children Born After Precipitate Labour, or Delivered in Ambulances or in the Absence of a Qualified Attendant*

Born After Precipitate Labour	Delivered in Ambulance	Delivered in Absence of Qualified Attendant
97·7 (2,985)	94·3 (250)	95·3 (981)

TABLE XVII.—*Mean V.R. Scores in Sib Pairs One of Whom Was Born After a Precipitate Labour, or Delivered in an Ambulance or in the Absence of a Qualified Attendant*

	Born After Precipitate Labour	Delivered in Ambulance	Delivered in Absence of Qualified Attendant
Affected children (a)	96·9	94·8	93·1
Unaffected sibs in subsequent birth rank (b)..	94·4	93·2	91·8
Difference (a)–(b)	+2·5 (200)	+1·6 (29)	+1·3 (107)
Affected children (c)	98·4	93·7	97·3
Unaffected sibs in preceding birth rank (d)..	98·9	96·9	97·4
Difference (c)–(d)	−0·5 (589)	−3·2 (90)	−0·1 (200)

Birth Attendant

Observations of the type of attendant present at birth—for example, hospital midwife or general practitioner—included cases where birth had occurred in an ambulance or before the arrival of a qualified attendant. The mean V.R. scores of the affected children are low (Table XVI). This may be partly or wholly the result of the known associations of inadequately supervised delivery with both precipitate labour and with poor social circumstances. The mean score of children born in ambulances is 1.6 above that of unaffected sibs in the subsequent birth rank, and 3.2 below that of sibs in the preceding birth rank (Table XVII). This is evidence of some direct association between impaired V.R. performance and birth in an ambulance. There is no evidence of a similar association with birth in the absence of a qualified attendant (Table XVII). The percentage distribution of children born in ambulances (Table XI) shows that a considerable excess of affected children (66%) have scores below the population mean (100.2).

Condition after Birth

This was recorded for 46,439 (95%) of the children. The mean V.R. score of children who had non-haemolytic jaundice is 100.2 (Table XVIII). Levels of serum bilirubin were not recorded. Table XIX shows that the mean scores of affected children are below those of sibs in the subsequent as well as the preceding birth rank; and this suggests that neonatal non-haemolytic jaundice is associated with an impaired V.R. performance. However, when comparison is restricted to sibs born at term (Table X) the association is no longer present, which suggests that it is secondary to the increased incidence of non-haemolytic jaundice among children born before term.

TABLE XVIII.—*Mean V.R. Scores According to Condition After Birth*

Non-haemolytic Jaundice	Birth Injury and/or Asphyxia
100·2 (903)	100·8 (909)

TABLE XIX.—*Mean V.R. Scores in Sib Pairs According to Condition After Birth*

	Non-haemolytic Jaundice	Birth Injury and/or Asphyxia
Affected children (a)	99·6	99·8
Unaffected sibs in subsequent birth rank (b)	100·0	95·1
Difference (a)–(b)	−0·4 (68)	+4·7 (56)
Affected children (c)	99·9	99·1
Unaffected sibs in preceding birth rank (d)	100·7	101·9
Difference (c)–(d)	−0·8 (117)	−2·8 (74)

A single coding was used to denote children who showed signs of trauma or asphyxia at birth. Therefore children who, for example, had cephalhaematomata, or were unusually cyanosed after birth, were coded in the same way. Such data permit only general conclusions. Nevertheless Tables XVIII and XIX provide no evidence that "birth injury and/or asphyxia" is related to academic performance in children within the normal range of intelligence.

Discussion

The results of this inquiry are based on an analysis of eleven-plus performance in a population of Birmingham-born children. This population did not include children who were of very low intelligence, who were in special schools for the physically handicapped, or who died before the age of 11 years. Children who had moved out of the city were also excluded, and the population was therefore unrepresentative of all eleven-plus candidates. However, it is difficult to see how this can affect the conclusions, which are mainly dependent on comparisons within fraternities.

Only five of the obstetric complications studied seemed to be associated with impaired V.R. performance: a short gestation period, a prolonged gestation period, toxaemia, occipito-posterior presentation, and delivery in an ambulance. Children born at term (38 to 41 weeks of gestation) had a higher mean V.R. score than children born after shorter or more prolonged gestation periods (Table IV); and comparison between sibs (Table V) suggested that in some cases impaired performance might be a direct consequence of birth before or after term. The results did not confirm those of Dale (1966), who, from a study of 179 children, concluded that "it is possible that a higher intelligence could be obtained by delivery before 40 weeks of gestation, provided the mother is obstetrically normal."

Children from toxaemic pregnancies were found to be at a great disadvantage compared with their unaffected sibs when they were born at term. The data did not permit further elucidation of this, but one interpretation of the finding is that induction of labour in cases of toxaemia may curtail a period during which the foetus sustains cerebral damage.

It it is accepted that the five obstetric complications—birth before and after term, toxaemia, occipito-posterior presentation, and delivery in an ambulance—do result in impaired academic performance among children at ordinary schools, it seems unlikely that they exert more than a small influence on the intellectual development of children exposed to them. The distributions of scores of affected children were unimodal (Tables VI and XI) and therefore provided no evidence of a substantial group of children whose development was greatly impaired; and there were only small differences in the mean scores of affected and unaffected sibs.

A previous analysis of the relation between obstetric complications and subnormal intelligence (an I.Q. below 75), based on the same obstetric data as the present analysis, revealed an association between educational subnormality and both precipitate labour and delivery in the absence of a qualified attendant (Barker, 1966). But neither of these complications seems to be associated with impaired performance within the normal range of intelligence.

The mean V.R. scores of children delivered instrumentally or by caesarean section were higher than those of the population and of their unaffected sibs. It seems reasonable to suppose that a child born by caesarean section may avoid cerebral damage sustained in a normal delivery; but it is difficult to explain the association between instrumental delivery and raised V.R. scores. The data are, however, too complex to justify the conclusion that instrumental delivery will improve school performance.

The finding that the mean V.R. score in the population declines with increasing birth rank (Table II) confirms numerous previous observations of the negative correlation between fraternity size and measured intelligence. But this inquiry has also shown that within fraternities there is an average fall of 1.0 in V.R. score with each unit increase in birth order.

Summary

Birth records of 50,000 children were linked with records of school performance at the age of 11. Twins and triplets showed marked impairment, and were excluded from this study. The verbal reasoning (V.R.) scores of single-born children exposed to obstetric complications were compared with those of the population and of their sibs. The results suggested that impaired performance was associated with only five of the obstetric complications studied: a short gestation period, a prolonged gestation period, toxaemia, occipito-posterior presentation, and delivery in an ambulance. In no case was the impairment very marked. Within fraternities there was a fall in average V.R. score with increasing birth rank.

It is a pleasure to thank Dr. E. L. M. Millar, Medical Officer of Health for Birmingham, and Sir Lionel Russell, Chief Education Officer for Birmingham, for permission to transfer records in their departments on to magnetic tape, and Dr. E. D. Acheson for lending a programme for converting names into the Hogben number. Computer Services, Birmingham, made their Univac 1107 available on generous terms; and we are particularly grateful to Mr. R. J. Milne for advice and for creating the tape files.

Paraproteins, Benign or Malignant?

J. R. HOBBS,[*] M.D., M.R.C.P., M.C.PATH.

Brit. med. J., 1967, **3**, 699–704

Paraproteins are those serum proteins which on electrophoresis are found to run as an abnormal narrow band between the positions occupied by the inter-α and post-γ protein fractions. Once it is confirmed that the paraprotein contains a heavy chain or a light chain, or both, of one class only—that is, a monoclonal immunoglobulin or fragment thereof—it may be assumed that it has come from a single clone of cells within the reticuloendothelial system. The question then remains, will this "monoclone" behave in a malignant fashion—invading bone (myelomatosis), lymphoid tissue (lymphomata), or the blood stream (leukaemia)—or will it, like a benign tumour, strike a balance with its neighbouring tissues and cause no harm to the patient?

Though much work (well reviewed by Hällén, 1966) has dealt with both malignant and benign conditions, less is known about the intermediate diseases owing to inadequate investigation during life or at necropsy. The present study includes 304 patients followed up to the time when a diagnosis of malignant disease was established or for at least three years. Prospective examination of fresh serum and urine from every patient has shown findings of prognostic value.

Investigation of Paraproteins

Serum

Serum was separated at 37° C. to avoid missing cryoproteins and then electrophoresed on cellulose acetate. False M bands due to fibrinogen or old or uraemic serum were excluded (Hobbs, 1966a).

The level of M protein was estimated as a percentage of the total uptake of amidoschwarz 10 *B* under standard conditions (Hobbs, 1965), great care being taken always to load the strip within a linear range, often set by the narrow bands of paraprotein. Strips were often run with decreasing applications until the percentage became constant. Usually no attempt was made to simulate peaks or subtract any underlying proteins—vertical cuts were made down the peaks. In this way reproducibility of ±2% was achieved. From the total protein by a biuret method (suitably diluted for high values) using Armour bovine albumin standard the percentage of paraprotein was converted to g./100 ml. in the case of γG, γA, and γD (where the dye-binding and biuret colour compared to albumin is reliable to within 5% overall). As the biuret method underestimates γM-paraproteins by 12%, the specific gravity gradient tube of Lowry and Hunter (1945) was used for determining the total protein in such cases. By the above technique pure isolated paraproteins calibrated by ultraviolet absorption could be added to normal serum and recovered with an absolute accuracy of ±0.2 g./100 ml.

By using our own monospecific rabbit antisera the presence of the paraprotein was confirmed by immunoelectrophoresis as an M bow of only one type of heavy or light chain, or both.

---

[*] Lecturer in Chemical Pathology, Postgraduate Medical School, London W.12.

After personally examining over 800 positive and very many negative samples, I have yet to see an M bow on immunoelectrophoresis that was not already apparent on cellulose acetate electrophoresis. Hence the latter method is a satisfactory screening test for paraproteins, though with paper electrophoresis small M bands can readily be missed.

In every case serum immunoglobulin levels of classes other than the paraprotein were measured by a modified Mancini method (Hobbs and Maatela, 1967), as a percentage of the mean level for that class determined in 107 normal adults. In Fig. 2 the average is plotted—for example, a patient with myelomatosis producing only Bence Jones protein had γG 44%, γA 50%, and γM 50% of mean adult normal; these results are plotted as "other immunoglobulins 48% mean normal."

γA-paraproteins have a shorter half-life (mean 6.4 days) than γG-paraproteins (mean 11.6 days) (Drivsholm, 1964); and for the same serum level have a faster turnover (10.8% of the total pool) than γG-paraproteins (6% of the total pool). Thus simple serum levels do not allow a true comparison between γA and γG classes. In order better to compare such patients, all of the latter have arbitrarily been assumed to weigh 70 kg., and to have a plasma volume of 50.7 ml./kg., and the plasma has been assumed to contain 71% of the total paraprotein pool —averages of available data in patients with myelomatosis (Gabuzda, 1962). Thus for a given serum level, M g./100 ml. the total pool would be $M/100 \times 70 \times 50.7 \times 100/71 = 50 \times M$ g.; and for patients in equilibrium the average daily productions of γA would be 10.8% of $50\ M = 5.4 \times M$ g. and of γG 6% of $50\ M = 3.0 \times M$ g. In γM-paraproteinaemia an average daily turnover is 13.3% of the intravascular pool of γM-globulin (Barth *et al.*, 1964), though these authors estimated the average plasma volume at only 45 ml./kg. Most of our patients were severely anaemic, so that an arbitrary plasma volume of 60 ml./kg. has been used, closer to that found in one patient of Gabuzda (1962) and in two patients of Olesen (1963). Thus, in equilibrium the daily production rate would be $M/100 \times 60 \times 70 \times 13.3/100 = 5.6 \times M$ g.

Any loss of Bence Jones protein was measured in a 24-hour specimen of urine; it was corrected for the patient's body weight and added to the above productions (or used by itself for patients producing only Bence Jones protein) to obtain the *approximate production of paraprotein* in g./70 kg. body weight/day. It is recognized that this value can be only approximate, since plasma and total body pools and the half-lives of paraproteins all show individual variation (mostly less than ±25% of the taken means) but this calculation is necessary to allow comparison of the different paraprotein classes in Fig. 2. Moreover, the large numbers of patients studied should help to overrule individual errors.

In Fig. 1 a value below the 2 S.D. lower limit of normal (for γG 54%, γA 52%, γM 50% of mean adult levels) has been recorded as "other immunoglobulins subnormal." This is particularly relevant for γM-globulin—which was the only protein having subnormal levels in 21 patients who were later found to develop a malignant process. This would not be detected simply by assessing the electrophoretic γ-globulin other than the paraprotein, as Hällén (1966) did.

Where desired the molecular sizes of the paraproteins were confirmed by using thin-layer Sephadex G200 (Hobbs, 1966a) or the ultracentrifuge.

Urine

Fresh urine (or preserved with toluene or azide) was examined in every case as follows. It was first cleared of bacteria by passage through a membrane filter with maximum pore size of 0.2 μ. Total protein was then measured by a biuret method on the redissolved precipitate from 10% trichloroacetic acid. Where significant, a 24-hour output was measured and the paraprotein content added into the total daily paraprotein production in Fig. 2.

The urine was suitably concentrated (up to ×500 within two hours by using Sartorius collodion shells attached to a vacuum pump) and electrophoresed alongside the patient's serum. Any M bands were measured as a percentage of the total protein and confirmed and typed by immunoelectrophoresis. When desired, the size of the M proteins was determined by using thin-layer Sephadex G75.

The interpretation of some of these methods has been described (Hobbs, 1966b) and, using them, it is easily possible to distinguish Bence Jones protein in the urine at concentrations of only 1 mg./100 ml. from normal light chains in the urine at concentrations of 0.25 mg./100 ml.

Biopsy Material

In some cases where serum and urine results were initially negative, bone marrow or other biopsy fragments (after thrice washing with 4% human albumin) were inserted into agar and then subjected directly to immunoelectrophoresis. In three patients with undoubted myelomatosis this investigation was negative. In two other patients positive results were obtained, and later confirmed by positive findings in subsequent sera and urine specimens. Hence this method is apparently the most sensitive test available.

Cold Agglutinins

All patients in whom γM-paraproteins were found were carefully investigated for cold agglutinins. Three patients proved to be suffering from primary cold-agglutinin syndromes and were not included in this study. The remainder did not have appreciable cold agglutinins present in their sera.

Material

All 146 patients whose initial specimens of sera and urine containing paraproteins were examined between October 1959 and June 1964 are included, together with a further 158 patients studied between June 1964 and March 1965 in whom a diagnosis was possible. The final classification of the patients' conditions was as follows:

I. Malignant	Myelomatosis	196
	Waldenström's macroglobulinaemia	19
	Lymphoma	6
	Chronic lymphatic leukaemia	2
II. Benign	Mainly static for at least three years ...	68
	Transient	2
III. Uncertain	... ...	11

I. Criteria of Malignancy

The assumed monoclone was thought to be malignant in 223 patients in whom the following diagnoses were established:

Myelomatosis (196 patients).—(1) Radiological evidence (87%)—discrete osteolytic lesions (61%), diffuse halisteresis with vertebral collapse or pathological fractures in the absence of other known causes (26%) (95% of these patients had a normal serum level of alkaline phosphatase). (2) Biopsy evidence—bone marrow or bone biopsy at operation or necropsy containing an excess of atypical plasma cells which in the opinion of the examining pathologist was characteristic of myelomatosis (92%). (3) Paraprotein detected in serum and/or urine and/or biopsy (γG 99, γA 50, γμ 41, γD 3) (98.5%). The diagnosis was never made on a single criterion only: in 78% all three were present, in the remainder at least two.

Waldenström's Macroglobulinaemia (19 patients).—(1) Severe lassitude with anaemia and neutropenia. (2) Bleeding unaccounted for by thrombocytopenia or a defect of clotting factors. (3) Mild to moderate splenomegaly, slight generalized lymphadenopathy. (4) Biopsy evidence—lymph nodes (architecture well preserved) and/or bone marrow infiltrated with atypical lymphoid cells consistent with the diagnosis in the view of the examining pathologist. (5) Monoclonal γM-globulin eventually greater than 2 g./100 ml.

Features 4 and 5 were found in every case, as were some or all of features 1–3. In eight patients atypical lymphoid cells were also found in the peripheral blood.

Lymphosarcoma (five patients: four γM, one γμ); *reticulosarcoma* (one patient, γA).—(1) Massive regional involvement of lymph nodes and/or spleen and/or liver. (2) Biopsy evidence—gross destruction of normal architecture by neoplastic lymphoid or reticulum cells. (3) In four patients unfixed material was studied with fluorescein-conjugated rabbit antisera specific to the heavy chain and light chain of the paraprotein class, which was thereby identified within the cytoplasm of scanty nests of cells within the tumour tissue. In all four cases only 5–15% of the tumour cell[illegible]e stained.

Chronic Lymphatic Leukaemia (two patients: one γG, one γμ).—(1) Peripheral blood lymphocyte counts above 40,000/cu. mm for over two years. (2) No evidence of bone lesions or involvement of lymph nodes, spleen, or liver. (3) Only the cytoplasm of a few of the circulating lymphocytes could be stained with fluorescent antibody specific to the paraprotein class.

II. Criteria of Benignity (68 patients)

(1) No symptoms related to the presence of paraproteins. (2) No palpable enlargement of lymph nodes, liver, or spleen. (3) Negative radiological survey, including at least the skull and axial skeleton. (4) Bone marrow—apparently normal or with an excess of plasma cells which, however, showed few, if any, atypical features. (5) Followed for at least three years, with no detectable change in the overall picture.

Transient (two patients).—The presence of a γG-paraprotein band was confirmed in the serum of each of these patients on at least three occasions. Nevertheless, the band disappeared within three and six months, and has not reappeared over two and eight years respectively. The first case has been reported in detail (Hobbs, 1966a) and neither is included in Fig. 1.

III. Uncertain (11 patients)

These patients had some of the features of malignancy—namely, clinical features (5) suggestive radiology (3), suspicious biopsies (7), recurrent infections owing to reduction of other immunoglobulins (4). Nevertheless, in no single patient could all the specialists concerned (physician, haematologist, radiologist, and biochemist) agree about the diagnosis, even by the end of the three-year period of observation—though it was agreed the condition could not be regarded as wholly benign.

Results

From Fig. 1 it can be seen that if at the initial examination findings (i), (ii), and (iii) were all present a diagnosis of malignancy was reached in all 109 patients. From the outset the diagnosis was in doubt in only 10 patients, and in them more definite evidence emerged within eight months. If findings (i), (ii), and (iii) were all absent the outlook appeared benign in all 58 patients three years later. Nevertheless, since this group of patients was selected for follow-up, one exceptional patient has been seen. He was first seen with a pain in the back due to collapse of a single vertebra; on investigation a γGK-paraprotein (0.2 g./100 ml.) was detected in the serum, but findings (i) and (ii) were absent. Skeletal survey and bone marrow were negative, but the vertebral biopsy revealed myeloma cells, and two years later there was evidence of recurrence; the serum paraprotein concentration had risen to 1.2 g./100 ml., while that of γM had fallen below normal.

	Benign condition	0	0	0	0	0	0	10	58
	Diagnosis still in doubt	0	3	0	0	2	6	0	0
	MALIGNANT CONDITION	100%	91%					9%	0%

FIG. 1.—Outcome in 302 patients with paraproteins. Positive findings are shown in black. If (i), (ii), and (iii) were all positive the outcome was malignant in every patient, whereas if they were all negative the patients appeared to have benign conditions three years later. Between these black and white extremes, positive findings (i) and (ii) had a poor prognosis because 91% of patients showing these have had malignant conditions. In cases where the initial diagnosis is in doubt, follow-up observation for finding (iv) is of great value.

Bence Jones Proteinuria

This was detected initially in 172 patients (Fig. 1). Of these, 170 have already developed malignant conditions, and this group represents 73% of the total of 223 malignant cases studied. It must be emphasized that if urine had not been concentrated and thoroughly examined Bence Jones protein would not have been found in 90 patients. Albustix cannot be used for this, while sulphosalicylic acid gave a negative result in 65. Careful layering of cleared urine over concentrated hydrochloric acid (Bradshaw, 1906) has been found to be unsurpassed as a screening test (Hobbs, 1966b), and the presence of a white ring at the junction of the urine and the acid indicated that 162 urines required electrophoresis.

Nevertheless, in the case of six specimens of urine Bence Jones protein was present at concentrations of between 120 and 1,200 mg./100 ml. (estimated only after precipitation with ammonium sulphate) but gave negative results with all the screening tests, was not precipitated by 10% trichloroacetic acid, and was found only by electrophoresis.

The most striking results have been found with the γM paraproteins. Bence Jones proteinuria was associated with 32 of the 34 malignant cases, though it was present at concentrations of only 1 to 20 mg./100 ml. in 26 patients; in the eight benign cases none was detected.

Other Immunoglobulins

Subnormal serum levels of one or more of the immunoglobulins of classes other than that of the paraprotein were found initially in 227 patients, and of these 218 proved to have malignant disease. Only five of 223 patients with malignant conditions had normal levels.

In γG-myelomatosis subnormal levels of γM- and γA-protein were found to be the rule (86 out of 99 patients); seven patients had a concentration of γM within normal limits, seven had a normal γA level, but only one patient had both normal γM and γA. Among 53 patients with γA or γD-myelomatosis, the level of γM was subnormal in 44 and of γG in 42, and only one patient had normal levels of both γM and γG. In myeloma producing Bence Jones protein only, the γM level was subnormal in 40 out of 41 patients: normal levels of γG and γA were found initially in 10 and 9 patients, respectively, but only one patient had concentrations of all three within normal limits. All three patients with undoubted myelomatosis, in whom no paraprotein could be detected, showed subnormal levels of immunoglobulins. Thus among 196 patients who developed myelomatosis only three had normal levels of the other immunoglobulins when first seen. For each immunoglobulin taken separately these results are very similar to those reported by Bachmann (1966), who, however, does not state whether the few patients with normal γA also had normal levels of γM and other proteins.

Of the first 19 patients seen with Waldenström's macroglobulinaemia, two had normal levels of the other immunoglobulins. Among the total of 34 malignant γM-paraproteinaemia (Fig. 2) the levels of γG and γA were within normal limits in 16 and 10, respectively, though only six patients had normal levels of both γG and γA.

In Fig. 2 it can be seen that, though the concentration of the other immunoglobulins tends to decrease as the daily production of paraprotein increases, the presence of γG-paraproteins is associated with the most severe reduction (even less than 10% with daily paraprotein productions below 10 g.). The reduction is not so severe with higher daily productions of γA, γM, and Bence Jones paraproteins. This reduction was especially associated with the malignant group, for the concentrations of the other immunoglobulins, though sometimes at the lower limits, have remained within normal limits in 68 patients in the benign group.

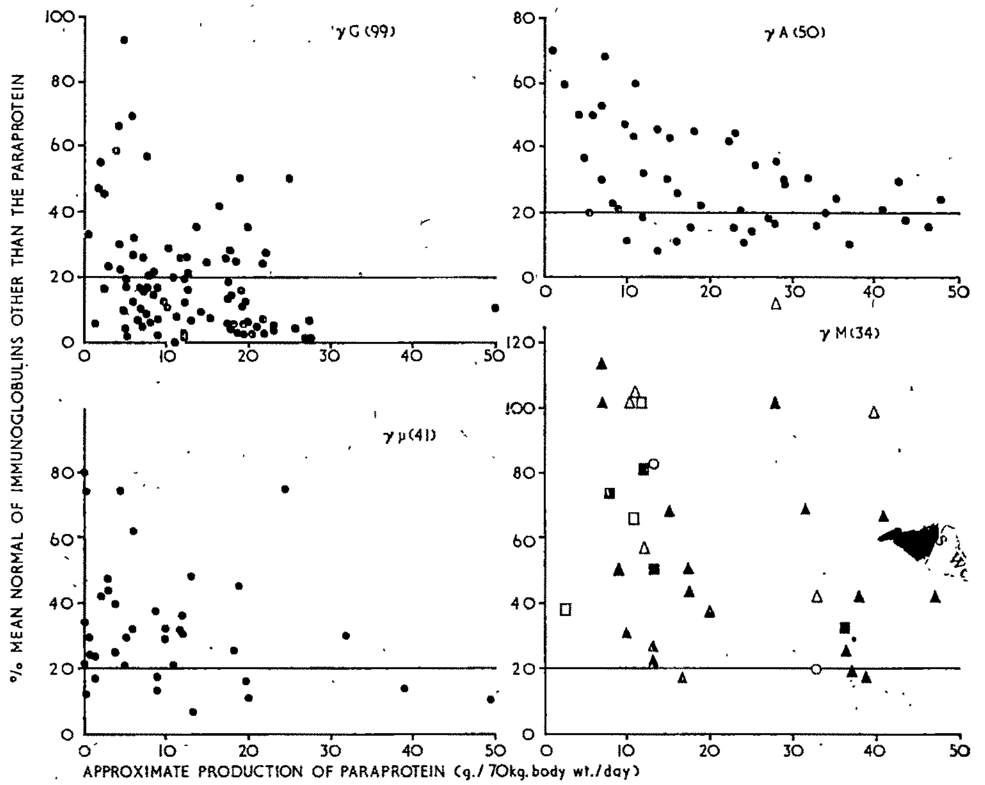

Fig. 2.—Reduction of normal serum immunoglobulins in relation to paraprotein production in patients with malignant conditions. Though there is some trend to lower values with increasing production, γG paraproteins are associated with the most severe reduction at lower production rates than γA and γM classes. The frequencies of patients under 20% agree with an increased incidence of infection presumably due to antibody deficiency (Hobbs *et al.*, 1966). Patients producing Bence Jones protein only (γμ, mostly without renal failure when first seen) present with lower production rates than the others, suggesting differentiation of their tumours. ●, Myelomatosis. ▲, Waldenström's. ■, Lymphosarcoma. (Open symbols indicate 11 additional patients (γM) not in the consecutive series.)

Levels of Serum Paraproteins

Apart from the 45 patients who produced only Bence Jones proteins, 175 patients with serum paraproteins were diagnosed as having malignant conditions, 161 (92%) of whom had levels greater than 1 g./100 ml. when first seen. This contrasts with the 68 patients whose conditions were regarded as benign, 58 (85%) of whom had levels of less than 1 g./100 ml.

Progress in Doubtful Cases

Of the 304 patients there were 110 in whom a firm diagnosis could not be reached initially. In these the paraprotein estimations were repeated at 3- to 12-monthly intervals. Within three years malignant conditions had developed in 29 patients, all of whom showed a significant (>0.2 g./100 ml.) and rapid increase in paraprotein level. In most cases only a second or third measurement was obtained before treatment was begun. Results in the patients who were followed the longest—and who clearly developed the bone lesions of myelomatosis—are shown in Fig. 3. By plotting the paraprotein level on a logarithmic scale against time on a linear scale, it can be seen that the rate of increase is exponential or only slightly curved: the doubling-time ranges from 4 to 25 months. This closely agrees with the data of Hällén (1966), many of whose 23 patients have had a longer follow-up: most of these showed exponential increases, and in 17 it was possible to estimate the doubling-time. Combining his results with the above nine, one obtains a median doubling-time of 12 months. The limit of likely detection of a serum paraprotein on cellulose acetate is about 0.2 g./100 ml. Average serum levels of paraprotein at the time of clinical presentation and diagnosis are γG 4.3 g./100 ml. and γA

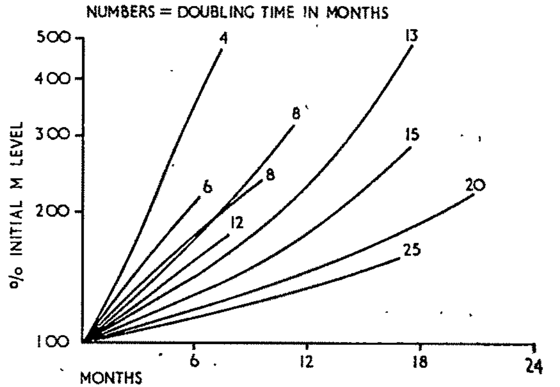

Fig. 3.—Progress in nine untreated patients in whom a diagnosis of myelomatosis was later established. The increasing serum paraprotein (M) level is shown on a logarithmic scale; there were at least four points on each line. The increase is exponential (straight line) or nearly so, enabling estimation of the doubling times in months as indicated above.

2.8 g./100 ml. (Hobbs *et al.*, 1966). Thus an exponential increase from the earliest serum level of chance detection to the average level when clinical diagnosis is certain could take between 18 months and nine years for γG and between 15 months and eight years for γA myelomatosis. Nevertheless, most patients will show significant increases (>0.2 g./100 ml.) in these levels within two years.

In contrast, 66 of the 68 patients classified as having benign conditions have not shown any persistent significant increase over three years. Two have shown increases (1.3 to 2.0 and 1.4 to 1.8 over three years). This finding again agrees well with that of Hällén.

Discussion

The natural frequency of the occurrence of serum paraproteins has been reported by Axelsson *et al.* (1966). Out of a population of 6,995, 64 subjects showed M proteins, and a malignant condition was at that time suspected in only four. Routine electrophoresis of serum obtained from 7,200 new patients at Hammersmith Hospital between December 1963 and June 1964 revealed the existence of 55 paraproteins. After three years' follow-up only 40% of these patients can be considered to have benign conditions, a malignant condition having been diagnosed in 53% and the diagnosis being uncertain in 7%.

From the results it can be seen that Bence Jones proteinuria in excess of 1 mg./100 ml. is of sinister significance. Of the normal daily production of 5 g. of immunoglobulin (Fahey, 1965) only 3.5 mg. (0.07%) appears as normal light chains in the urine, in a concentration of about 0.25 mg./100 ml. (Berggard and Edelman, 1963). Thus an increase in light-chain excretion reflects an inefficient process and probably implies that the synthesizing cells have lost their differentiation. The production of Bence Jones protein indicates further dedifferentiation and the prognosis is worse. These patients present with lower daily paraprotein production rates than those for the other classes (see Fig. 2), and most are dead within six months of diagnosis, though one exceptional patient who survived 15 years has been seen.

The other feature signifying an adverse prognosis is the loss of normal immunoglobulins, originally emphasized by Grabar *et al.* (1956). In four patients a severe reduction in immunoglobulin levels was detected one to three years before the malignant clone was large enough to produce detectable lesions or paraproteins (premyelomatosis).

The mechanism of the suppression of immunoglobulin production remains unknown. Displacement of normal antibody-producing cells seems unlikely; indeed, the production of γA-globulin—which is derived largely from the gut—may be severely reduced with no regional involvement of the gut. The presence of an excess of γG-paraprotein resulted in an increased turnover and a reduced level of normal γG-globulins in six out of the 11 patients studied by Solomon *et al.* (1963). Nevertheless, turnover of γM-globulin has not been shown to be affected (Barth *et al.*, 1964), so that increased catabolism cannot account for the usual severe reduction of γM-globulin levels. It seems probable that the synthesis of γM-globulin is impaired, as is that of γA-globulin. In two patients removal of an apparently solitary myeloma was found to restore the levels to normal (Hobbs, 1966a), and this suggests that the tumours release some humoral substance which inhibits the synthesis of normal immunoglobulins but not that of paraproteins.

Nathans *et al.* (1958)—confirmed by Osserman *et al.* (1964)—found that in mice there was a linear relation between the amount of plasmacytoma and the serum level of γ-paraprotein—which was produced at a daily rate of about 14 mg./g. well-differentiated tumour. This roughly agrees with the estimated rate of production of antibody by single cells (Nossal and Mäkelä, 1962). On average, patients with γG-myeloma have a serum level of this paraprotein of 4.3 g./100 ml. when first seen, and produce some 13 g. of paraprotein daily. This total production could require 930 g. of tumour to be present. Harrison (1962) estimated that for a 70-kg. man the total bone-marrow cellularity was 7.5×10^{11} cells. If the haemopoietic tissue is assumed to weigh a total of 1,625 g., each 1 g. would contain 4.6×10^8 cells, and 930 g. of γG-myeloma tissue could contain 4.3×10^{11} cells. The average 60-kg. man would have a bone marrow of 3,250 g. (Mechanik, 1926). Normally about half is haemopoietic. Patients with γG myeloma have on average 42% myeloma cells in bone marrow biopsies—that is, 685 g. if half the marrow is haemopoietic or 1,370 g. if the marrow is fully occupied. The independent estimate is similar to that based on paraprotein production. If the myeloma tissue is a clone derived from a single cell then it would take almost 39 doubling divisions to reach this number of surviving cells. If we now accept, in man as in the mouse, that the doubling-times of paraprotein levels (4–25 months, Fig. 3) reflect the doubling-times of the cells producing them, it could take 13 to 80 years before the amount of γG-myeloma was sufficient to produce symptoms.

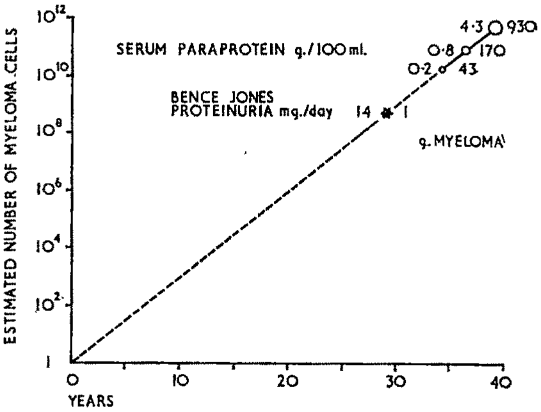

FIG. 4.—Schematic development of myelomatosis. The solid part of the line shows the observed exponential increase of serum paraprotein level from the lowest detectable level of 0.2 to the average level of 4.3 g./100 ml. found in patients presenting with γG-myelomatosis. At the median doubling-time of 12 months this would take about five years. The star indicates the earliest possible detection of myeloma 10.7 years before the usual time at this doubling rate. If it is assumed that the serum level reflects the myeloma mass and its contained cells, the extrapolated broken line shows that if it arose from a single cell and grew at the same exponential rate throughout it began some 39 years previously.

Hence chance detection of a serum paraprotein might not occur for 11 to 70 years (see Results)—though an isolated lesion, such as the collapse of one vertebra or the finding of Bence Jones proteinuria, could reveal the presence of an early myeloma, which might then take up to 20 years to declare itself clinically. These conclusions are summarized in Fig. 4 for a median doubling-time of 12 months: the dotted portion of the line is speculation based on results in the mouse. Similar extrapolations have offered accurate explanations for the latent periods observed between irradiation of humans and the subsequent clinical emergence of acute leukaemia and thyroid cancer (reviewed by Hobbs, 1963).

Such estimates assume that the growth of the cells is exponential throughout, and this is not always the case. Some tumours outgrow their blood supply and undergo necrosis, but myeloma is well placed to avoid this, though a change in growth rate has been seen in two patients. Furthermore, these estimates apply only to well-differentiated tumours, in which virtually all the neoplastic cells eventually produce paraprotein. Our own experience with fluorescent antisera suggests this is so in most cases of myelomatosis, though in the mouse Osserman *et al.* (1964) found that after multiple passages the cells comprising the plasmacytoma could become considerably less differentiated, producing less paraprotein and growing faster. A few patients with obviously extensive rapidly growing myeloma similarly produce little or even no paraprotein, especially those who produce only Bence Jones protein.

In lymphosarcomata and in chronic lymphatic leukaemia, on the other hand, it seems to be the rule that when paraprotein production occurs it involves only a small percentage of the tumour cells. MacKay *et al.* (1957) thought that the presence of macroglobulinaemia in such cases was a secondary phenomenon, and arose from a side-line of mutated cells. The presence of more than one paraprotein has been demonstrated in three of our six patients with lymphomata—an incidence that is in marked contrast to our findings in myelomatosis, five out of a total of 320 patients showing more than one paraprotein. These findings also agree with those of Imhof *et al.* (1966), and support the hypothesis that paraprotein production in the lymphomata reflects unstable, mutating cell populations.

Paraproteins are also found in association with other malignant diseases, but their frequency is no greater than would be expected (Hällén, 1966). Moreover, their levels rarely correlate with the removal or progress of the cancer, and our own experience suggests that this largely occurs by chance.

Summary

Examination of blood and concentrated specimens of urine for paraproteins, together with the measurement of the other immunoglobulins, can have prognostic value in some groups of patients. In doubtful cases, following the paraprotein level can indicate within one to three years which cases are likely to show malignancy, though up to 10 years may be required before the diagnosis is certain, and up to 20 years where solitary lesions or only a trace of Bence Jones proteinuria are the presenting features.

This article would have been impossible without the participation and encouragement of the Medical Research Council and its Myeloma Trial Working-party. Many other patients have been referred from other physicians, particularly my colleagues at Hammersmith, who have kindly provided full details and follow-up data. I am indebted to the staff of the haematology and radiological departments. I would also like to thank Professor I. D. P. Wootton, Professor J. V. Dacie, and Dr. D. A. G. Galton for their guidance ; Miss Hazel Gardner, Miss Susan Burtenshaw, and Mrs. Ann Kasler for their assistance ; and Mr. K. B. Cooke for early guidance in immunoelectrophoresis.

Lymphocyte Transformation and Chromosome Studies in Hodgkin's Disease

SYLVIA D. LAWLER,* M.D., M.C.PATH. ; C. R. PENTYCROSS,† M.B., B.CH. ; B. R. REEVES,‡ B.SC.

Brit. med. J., 1967, 3, 704–708

The circulating lymphocytes in Hodgkin's disease are assumed to be immunologically deficient because of the poor response shown by the patients in delayed hypersensitivity tests. There is some evidence that this anergy is present even in the earliest stages of the disease (Aisenberg, 1965). The question therefore arises whether the lymphocytes are also abnormal in any other respect.

One way of testing a population of lymphocytes is to study the responses to stimulation in vitro by phytohaemagglutinin. When normal lymphocytes are cultured with phytohaemagglutinin a high proportion are stimulated to divide, and a cell showing the associated morphological changes is said to have "transformed." Recent studies (Hersh and Oppenheim, 1965) have shown that the response of the lymphocytes in Hodgkin's disease is sometimes depressed. At least three factors may influence the response: the lymphocyte count, which is often very low ; the stage of the disease at the time of investigation ; and the effects attributable to radiation or chemotherapy. We have attempted to assess the relative importance of these factors.

Another way of characterizing a cell population is to determine the chromosome complement. Apart from a single case of Spiers and Baikie (1966), in which the peripheral blood lymphocytes were found to be normal, no information about the chromosomes of the circulating lymphocyte in Hodgkin's disease is available. There is no doubt that chromosomal abnormalities are detectable in lymph node material (Ricci *et al.*, 1962 ; Spriggs and Boddington, 1962 ; Galan *et al.*, 1963 ; Baker and Atkin, 1965 ; Miles *et al.*, 1966 ; Spiers and Baikie, 1966). Various abnormalities have been described, including polyploid cells, presumed to represent Sternberg-Reed cells, and anomalous chromosomes, particularly of the E group, in diploid cells.

Materials and Methods

Twenty cases have been studied. Some of the patients are the same as those investigated by Goldman and Hobbs (1967). The method used in the lymphocyte transformation tests is that

described by Pentycross (1967) in which the final concentration of cells in culture is 10^6/ml. The phytohaemagglutinin cultures are harvested after 72 hours.

The chromosome and transformation studies were carried out on aliquots of the same blood samples. Microcultures using a slight modification of the method of Arakaki and Sparkes (1963) were often unsuccessful. Better results were obtained when suspensions of separated lymphocytes were used. The method was based on that of Moorhead *et al.* (1960), the polymorphs being removed by carbonyl iron (Carstairs, 1962). The preparations were fixed in 3 : 1 methyl alcohol and glacial acetic acid and the slides made by dropping a suspension in 45% acetic acid on to cold slides, which were then allowed to dry on a warm plate.

Results

Response to Phytohaemagglutinin

The percentage of transformed cells in the cultures from the patients ranged from less than 1 to 56 (transformation score). In our laboratory the score for normal people is 36–60%. Many workers quote a higher score than this for normal lymphocytes. In our laboratory at least 4,000 cells are counted from each culture by scanning the slides in systematic strips. This scoring method gives a result representative of the entire cell population in the culture.

In assessing the cultured lymphocytes *qualitatively,* two types of anomalous cell, which are only rarely seen in normal controls, were found to occur with increased frequency. (1) Large, probably transformed, cells having a bizarre nuclear pattern and ragged pale cytoplasm. The nucleoli (almost invariably present) were amorphous, basophilic, and completely circular. (2) Cells the size of small and medium lymphocytes with amorphous nuclei.

In some instances, moreover, the majority of transformed cells satisfied only the morphological criteria (stippling of nuclear chromatin, visible nucleoli, large size, and cytoplasmic basophilia) to a limited degree.

Anomalous cells and poorly transformed ones were found predominantly in association with transformation scores of less than 30%.

The patients have been arranged in the Table according to the transformation score. When a patient was tested a second time the higher score decided the position in the table.

The clinical staging (column 5 in table) was that of Peters (1950), modified by Kaplan (Karnofsky, 1966), as follows:

Stage 0: no detectable disease owing to excisional biopsy.

Stage I: disease localized to a single node and contiguous structures without systemic symptoms.

Stage II: disease limited by the diaphragm to the upper or lower half of the body, but at more than a single site.

Stage III: disease above and below the diaphragm.

Stage IV: disease demonstrated in any one of the following areas: bone marrow, pulmonary parenchyma, skin, gastrointestinal tract, or bone.

Stages II and III are subdivided into A and B, with or without symptoms of generalized disease respectively.

These stages depend, to a large extent on visible or palpable masses which do not necessarily relate to the total tumour bulk.

The information in the Table may be summarized as follows:

(*a*) There is some correlation between the percentage of transformed cells in the cultures of peripheral blood lymphocytes and the clinical staging. Thus the five patients in stages 0–I all had scores between 32 and 52%. On the other hand, the scores for the 15 patients in stages II–IV ranged from less than 1% to 56%, though all the patients with a score of less than 12% of transformed cells were staged at least as IIB.

(*b*) Age and length of history appear not to have influenced lymphocyte response to any significant degree.

(*c*) Of the two untreated patients, one (Case 1) had a transformation score within normal limits, and the other (Case 12) a score just below normal. However, chemotherapy and recent *local* irradiation do not appear to have contributed to any extent to the depression of the lymphocyte response in this series.

(*d*) Some of the patients with lymphopenia (less than 1,500/ml.) had low transformation scores. Virtually all those with transformation scores of 12% or less were lymphopenic. However, a normal lymphocyte count was not necessarily associated with scores in the normal range.

(*e*) With one exception (Case 9), there was no significant difference in transformation score when tests were performed twice on any one patient.

Chromosome Studies

The results of the chromosome studies are given in column 9 of the Table. Only those cells which did not show features suggesting radiation damage were analysed in detail, but all cells appearing in the Table were scored for the presence of secondary constrictions in the paracentric third of the long arms of chromosome C9.

Mitotic yields were poor in patients with a low score in the transformation test. Good mitotic yields were obtained in the cultures in Cases 6 (*b*) and 11, but only a few cells were of sufficient quality for analysis. This explains the discrepancy in these cases between the response of the lymphocytes to phytohaemagglutinin and the amount of data on the chromosomes.

In the series as a whole 19 cells out of 89 analysed were aneuploid. Twelve of these aneuploid cells were contributed by two patients (Cases 3 and 14). Rearranged modal cells were found in Case 3 but not in Case 14. Concurrently 89 cells were analysed from lymphocyte cultures of three normal individuals (covering the age range of patients in the study) and nine were found to be aneuploid.

In one untreated patient (Case 1) a hypomodal cell was found which contained a marker chromosome resembling a B-group chromosome with most of the short arms missing.

Some polyploid cells, not suitable for analysis, were seen in three patients (Cases 2, 3, and 11). The most likely cause of an increased number of polyploid cells is previous treatment with irradiation (Buckton *et al.*, 1962); it is unlikely that these cells represent circulating Sternberg–Reed cells.

The criteria for assessing radiation damage were based on the data of Buckton *et al.* The aberrations seen in our material were fragments, dicentrics, and chromosomal rearrangements. Cells showing features of radiation damage were seen in two patients (Cases 13 and 14) who had been treated with vinblastine sulphate but not by irradiation. The possibility arises that the damage was due to the action of vinblastine in vivo, but we have been unable to produce chromosome breakage in normal lymphocyte cultures in vitro with vinblastine even with concentrations as high as 100 μg./ml. of culture medium.

In two patients (Cases 3 and 13) an apparent dicentric chromosome formed by an end-to-end association of two chromosomes was observed. In Fig. 1 the D/F associated chromosome of Case 3 is shown; with this associated chromosome separated, the cell had a normal karyotype. In Case 13 (Fig. 2) the association was between A3 and G21-22, but the cell showed evidence of radiation damage. This type of association is not generally recognized as a radiation effect, but it has been described in cultures of cells infected with virus (Moorhead and Saksela, 1963). Marker chromosomes composed of two chromosomes in an end-to-end association have been observed in testicular tumours from untreated patients (Martineau, 1967).

Secondary constrictions were seen in 11% of C9 chromosomes in the normal controls previously mentioned. Among the patients, constrictions were present in 35% of available C9 chromosomes. An example of a constricted C9 chromosome

Key to Table

Column 1.—( ) = Number in series of Goldman and Hobbs (1967). (a) = First test. (b) = Second test.
Column 5.—O-IV = Clinical staging of Peters (1950), modified by Kaplan (Karnofsky, 1966). A = No symptoms. B = Symptoms of generalized disease.
Column 6.—M = Mustine hydrochloride. CP = Cyclophosphamide. VLB = Vinblastine sulphate. CB = Chlorambucil.
Column 7.—T = Total W.B.C. L = Lymphocytes.
Column 9.—Ex. = Exaggerated or attenuated secondary constrictions. N = Normal diploid. N.M. = No mitoses. N.A. = No cells suitable for analysis. M = Marker chromosomes. [ ] = Damage of radiation type

from a lymphocyte culture of a normal control, when using the same technique of culture, is shown in Fig. 3. Some of the constrictions obtained in the cultures of the patients were exaggerated and sometimes markedly attenuated, and in the Table these are indicated by the abbreviation Ex. An example of an attenuated constriction is shown in Fig. 4, and the tendency for acrocentric chromosomes to associate with such regions (Ferguson-Smith and Handmaker, 1963) is shown in Fig. 5. No exaggerated constrictions were seen in normal controls.

Discussion

Response to Phytohaemagglutinin

There does seem to be a correlation between the clinical staging and the transformation scores. However, as noted already, the clinical staging may not precisely reflect the severity of the disease, since it depends on a visual assessment of the amount of disease present, which may bear no relation to total tumour bulk. A lymphangiogram, which is a useful test, especially for distinguishing stage II from stage III, was not always carried out on these patients.

The partial association between the lymphocyte count and the transformation score provides an interesting contrast to the situation existing in chronic lymphocyte leukaemia where there is a correlation between a high total lymphocyte count and a low transformation score (Hayhoe *et al.*, 1967). In the latter disease it would seem that there is a large population of lymphocytes which are unresponsive to phytohaemagglutinin, and therapy preferentially eliminates these. It is possible that in Hodgkin's disease there is a progressive reduction in both the numbers of lymphocytes and their responsiveness.

Local irradiation does not seem to have influenced the transformation score. Millard (1965) established that large doses of irradiation, not localized, may depress lymphocyte transformation for variable periods after cessation of therapy.

There may possibly be other (as yet unknown) factors. Case 7 was tested when in stage IIIB, and in fact died within three months, and yet his cells transformed moderately well. Case 9 differed in no way clinically or haematologically on the two occasions she was tested, but the transformation score varied between 3 and 36%.

Chromosome Studies

As might be expected when the response to phytohaemagglutinin is depressed, only few cells, if any, were available for analysis in patients with low scores in the transformation test. Suspension cultures proved more successful than microcultures. The failure of microcultures in lymphopenic patients can be attributed to the fact that an excessive number of red cells must be included in order to have an adequate number of lymphocytes.

In this series, more aneuploid cells were observed than were found in normal controls. This observation could be accounted for, at least in part, by radiation effects. There was no evidence for the circulation of a population of lymphocytes with abnormal chromosome complements. With the exception of the marker chromosome present in one cell of Case 1, no abnormal chromosomes resembling those observed in diploid cells obtained from lymph node material were seen.

In most cases the number of hypomodal cells was compatible with the assumption that they were randomly broken cells. The number of hypomodal cells in two patients (Cases 3 and 14) was significantly higher than in normal controls. This does not necessarily mean that a tendency to errors in division had produced the aneuploidy. Such a result could also be observed if the cells were more easily broken by the standard procedure than normal ones. The rearranged modal cells in Case 3 could not obviously be attributed to irradiation, but it is a possible cause, since Buckton *et al.* (1962) showed an increase in aneuploidy which continued for many years after *x*-ray treatment had been completed. In Case 14, treatment with vinblastine may have been the cause of increased aneuploidy. It is rare to find hypermodal cells in normal controls, but though one hypermodal cell was found in each of three patients the significance of this is difficult to assess because of the low mitotic yield.

The number of radiation-damaged cells observed was within the range described for lymphocytes in patients irradiated for other diseases.

The presence of prominent secondary constrictions in C9 chromosomes has been observed in lymph node material from patients with lymphomas (Miles *et al.*, 1966). In this laboratory, cells from a node of a patient with Hodgkin's disease, additional to those in the series, showed constrictions in 16 (38%) of the available C9 chromosomes when cultured with phytohaemagglutinin. Four of these constrictions were exaggerated.

This feature of increased frequency and prominence of secondary constrictions in the chromosomes of lymphoid cells is not restricted to Hodgkin's disease, since we have also observed it in patients with other malignant lymphomas and plasmocytoma. In assessing the significance of this observation certain facts have to be taken into account. These constrictions can be observed in lymphocyte cultures from normal individuals with a lower frequency, but it is extremely rare to find them in the attenuated form shown in Figs. 4 and 5. The frequency and the appearance of these constrictions can be altered in cultures of normal cells by varying the proportions of methyl alcohol and acetic acid in the fixative (Saksela and Moorhead, 1962), but in the present study the fixative was maintained throughout at the standard concentration. Cells treated with SV 40 virus in culture (Moorhead and Saksela, 1963) or with mitomycin C (Cohen and Shaw, 1964) or bromodeoxyuridine (Kaback *et al.*, 1964) also show an increased number of secondary constrictions. The appearances of the attenuated constrictions seen in the present study resemble the effect produced by the addition of mitomycin C to in-vitro cultures of lymphocytes. In this context it is interesting to note that mitomycin C, in causing chromosomal breakage in vitro, shows a preference for the areas of secondary constrictions. In this respect it differs from the other agents that have a random effect, though some of these may induce increased frequency of secondary constrictions.

The occurrence of secondary constrictions is not restricted to C9 chromosomes, but in this study it is the quantitative increase and attenuation in this particular chromosome that is most notable. The effect cannot be regarded as a specific one because it has been observed in patients with malignant lymphoma of different histological patterns and it is an exaggerated expression of a normal feature of the chromosomes. The enhancement of the secondary constriction in these diseased states is probably not due to treatment, since it can be observed in untreated cases. The association between lympho-proliferative disorders and the prominence of these regions of the chromosomes which are peculiarly sensitive to alteration by the action of certain chemical agents may have some relevance to the choice of drugs to be used in treatment.

Summary

The characteristics of the circulating lymphocytes in Hodgkin's disease have been investigated in 20 patients. The methods used were (1) in vitro response to phytohaemagglutinin and (2) chromosome analysis.

Transformation Studies.—The percentage of the lymphocytes that transformed morphologically after stimulation with phytohaemagglutinin varied between less than 1 and 56 (normal controls 36–60%). The depression of response was correlated to some extent with the severity of the disease. In some instances a low transformation score was associated with total lymphopenia. The depression of response did not appear to depend on current or previous treatment. It was concluded that the deficiency in response is one of the manifestations of the disease.

Chromosome Studies.—Mitotic yields were often low, but better results were obtained with suspension cultures than with microcultures. Most of the aneuploid cells, or cells with anomalous chromosomes, which we observed could be attributed to the effects of treatment. The frequency of radiation damage was within expected limits as compared with patients irradiated for other diseases. An increased frequency of constrictions in the C9 chromosome and the occasional exaggeration of this constriction was observed. This represents a modification of a feature present in normal cells and is by no means specific to Hodgkin's disease, since it has been observed in lymphoid cells in cases of other malignant lymphomas and in plasmocytoma.

The studies gave no indication of the circulation of a population of chromosomally abnormal lymphocytes, the majority of cells analysed having a normal chromosome complement.

We wish to thank Dr. L. Szur for permission to study his patients at the Hammersmith Hospital, and the consultant staff at the Royal Marsden Hospital for access to their patients; Dr. J. M. Goldman and Dr. J. R. Hobbs for their co-operation; and Dr. D. A. G. Galton for his valuable criticism of the manuscript.

C. R. P. gratefully acknowledges a grant from the Leukaemia Research Fund Ltd. in support of his work.

Mushroom-worker's Lung

ALEX SAKULA,* M.D., M.R.C.P.

[WITH SPECIAL PLATE BETWEEN PAGES 708 AND 709]

Brit. med. J., 1967, **3**, 708–710

In recent years the increased demand for mushrooms as a table delicacy has led to the development of intensive methods of cultivation in mushroom-growing farms. Many workers are at present involved in mushroom growing, and are therefore exposed to any potential hazard which might be associated with the process.

Mushroom growers have themselves been aware of the occasional development of various symptoms during the course of their work, but the only medical report of these was by Bringhurst *et al.* (1959), who described a respiratory disease among 16 immigrant Puerto Ricans working in the "Chester" County area of Pennsylvania, where 90% of the mushrooms consumed in the United States are cultivated. No special reports of similar cases have appeared since then.

In this paper four cases are described of mushroom workers in Sussex (where 50% of English mushrooms are cultivated) who developed respiratory disorders thought to be related directly to their occupation.

Mushroom Cultivation

The common edible mushroom, *Agaricus hortensis* (or *Psalliota bispora*), is grown on natural compost, consisting of a mixture of wheat straw and fresh horse manure, which is allowed to become partially decomposed or composted. This composting takes place in two phases.

In phase 1, carried on outdoors, stacks of compost are exposed to the atmosphere for three weeks. In phase 2 the compost is placed on to large wooden trays, introduced into closed chambers, and subjected for several days to a peak heat of 55–60° C., and 100% humidity, produced by blowing live steam into the chambers. This pasteurizing process kills off the pests and organisms which would interfere with the growth of the mushrooms. Various thermotolerant and thermophilic actinomycetes find the conditions of both phases of the composting process conducive to their growth.

The compost is then cooled to 25° C., and planted with specially prepared mushroom mycelium grown on manure or grain (known as spawn). This spawning process is usually

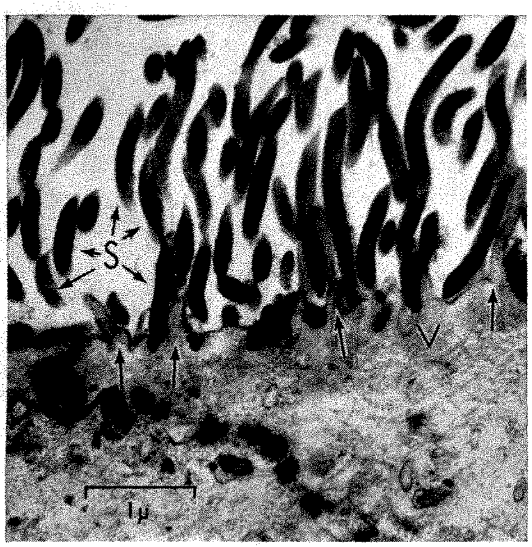
W. A. HARLAND AND F. D. LEE: INTESTINAL SPIROCHAETOSIS



Surface of two epithelial cells with numerous spirochaetes (S) orientated in the long axis of the cell. Arrows indicate microvilli. V is a reactive vacuole.

carried out by hand, either direct into the compost or by broadcasting the spawn on to the trays. The spawn is then mixed mechanically with the compost (through spawning), this process producing some disturbance of the compost with liberation of dust. Spawn running then occurs, the temperature being maintained at 20–25° C., with 90% humidity.

The compost in the trays is then covered or cased with a thin layer of peat-chalk mixture, which has previously been sterilized by heat or chemicals. This casing is necessary to encourage the fruiting of the mushrooms. The trays are then placed in the mushroom sheds, where the temperature is kept steady at 15° C. and the humidity at 80–90%, careful ventilation being maintained. The first growth or cropping will usually take place three weeks later, and the picking and packing of the mushrooms begins. Fresh flushes of mushrooms appear at weekly intervals, usually for six weeks. To prevent various parasitic diseases which might damage the mushrooms, various bactericides and fungicides—for example, formaldehyde—and pesticides and insecticides—for example, D.D.T. —are sprayed into the mushroom sheds. After the final picking the mushroom sheds are cooked out at 60° C., and the trays are emptied of the compost, which is dumped in a field.

It is during the spawning operation and when the mushroom sheds are emptied that most dust is liberated.

Case 1

A man aged 44 started work at a mushroom farm in November 1965 and was chiefly concerned with the spawning process. A month later he began to feel dizzy, developed headache and generalized muscle aches, and vomited. Cough and sputum ensued, and he became dyspnoeic on effort, with pain in the chest. When first seen in December 1965 he had ceased work, his symptoms were already subsiding, and there were no abnormal physical signs detectable in the chest. The chest radiograph showed a diffuse miliary mottling throughout both lung fields, the hilar shadows looking prominent (Special Plate, Figs. 1 and 2). Sputum culture produced a mixed growth of organisms; *Myobacterium tuberculosis* was not isolated. The tuberculin test was positive. W.B.C. was 8,000/cu. mm. (neutrophils 63%, lymphocytes 31%, monocytes 5%, eosinophils 1%); E.S.R. 8; serum proteins 6.4 g./100 ml. (albumin 4.1 g., globulin 2.3 g.). Skin allergy tests (including *Aspergillus fumigatus*) were negative. Serum precipitin tests were positive to *Micromonospora vulgaris* and negative to *Thermopolyspora polyspora* and to *A. fumigatus.*

During the ensuing month his symptoms cleared completely and the chest radiograph returned to normal. He ceased work on the mushroom farm, but when seen a year later, in April 1967, he was still bothered at times by undue dyspnoea and chest pain. A repeat of the serum precipitin test was negative to *T. polyspora.*

Case 2

A man aged 49 started work at a mushroom farm in February 1965. In December 1966 he became unduly dyspnoeic on effort, and developed cough and purulent sputum, these symptoms tending usually to be worse on Wednesdays, when he was engaged on spawning. The symptoms generally cleared by the week-end, only to return on the following Wesdnesday, when he needed to perform the spawning process again. His dyspnoea became so marked that he required to be admitted to hospital for one month, by the end of which time his condition had improved. On return to his former work, however, the respiratory symptoms at once occurred.

When first seen in February 1967 there were no abnormal physical signs in the chest. Chest radiographs showed a diffuse mottling in both lung fields, chiefly in the lower halves, but the hila were not prominent (Special Plate, Figs. 3 and 4). Sputum culture produced a light mixed normal growth. Culture for fungi was negative. *M. tuberculosis* was not isolated. The tuberculin test was negative. W.B.C. was 8,700/cu. mm. (neutrophils 67%, lymphocytes 29%, monocytes 4%); E.S.R. 13. Pulmonary function tests showed peak flow rate 415 litres per minute, forced vital capacity 4.05 litres, and forced expiratory volume in one second 3.25 litres (77% of F.V.C.). The serum precipitin test was positive to *T. polyspora.*

He remained away from his work and soon lost his respiratory symptoms; within two months the chest radiographs showed the lung mottling to have cleared completely.

Case 3

A man aged 47 was first seen in October 1960. He had been working at a mushroom farm for six months, being chiefly involved with the spawning process. He gave a six-weeks history of dyspnoea, this developing after what he had thought to be an "influenzal" illness. He was troubled by a spasmodic cough, little sputum, and attacks of dyspnoea several times daily. He felt weaker, had night sweats, and his weight dropped by 10 kg. Crepitations were audible over both lung bases. Chest radiographs showed a marked diffuse fine mottling, chiefly of the lung bases, to the extent that there was a "ground glass" effect, and the hilar shadows were prominent (Special Plate, Figs. 5 and 6). Sputum culture produced a mixed growth of organisms. *M. tuberculosis* was not isolated. W.B.C. was 4,500/cu. mm. (neutrophils 64%, lymphocytes 30%, monocytes 3%, eosinophils 3%); E.S.R. 18. The tuberculin test was positive. Skin allergy tests (including moulds and mushrooms) were negative.

After receiving penicillin and streptomycin by injection for one day he was remarkably improved. The antibiotics were discontinued, as it was thought that the rapid recovery suggested the subsidence of some sensitivity reaction rather than an infection. He returned to his former work, but was immediately troubled by bouts of dyspnoea, especially at night. Chest radiographs continued to show the mottled appearance at the lung bases. Treatment with prednisone was therefore started, and when seen a month later he had improved.

He returned to work at the mushroom farm, but was taken off the spawning process, though he remained in contact with the compost when emptying the trays and disposing of the used compost. When seen some years later, in April 1967, he was still bothered by undue dyspnoea and occasional chest tightness. Chest radiographs showed clearing of the mottling, though the right lung base looked fibrotic. Serum precipitin tests were negative to *T. polyspora* and *A. fumigatus.*

Case 4

A girl aged 17 was first seen in August 1960. She had been employed as a picker and packer in the mushroom sheds since leaving school at the age of 15. She had become subject to episodes of dizziness and cough for several months, but one week before being seen she developed anorexia and nausea, after which she became dizzy and more easily dyspnoeic, and chest pains developed. She had a cough, with purulent sputum, at times blood-stained. In addition, an irritating maculopapular rash appeared on the trunk and limbs. These symptoms developed within a few hours of entering the mushroom sheds, and cleared spontaneously after 48 hours' avoidance of the sheds. Clinical examination of the chest did not reveal any abnormal physical signs, and the chest radiograph looked normal. At first she was thought to have a simple bronchitis and and was treated with tetracycline, with improvement.

A month later she returned to her former work, but on re-entering the mushroom sheds she fainted on two occasions. Further investigation showed the chest radiograph to remain normal. Sputum culture grew normal flora. Culture for fungi was negative. *M. tuberculosis* was not isolated. The tuberculin test was negative. W.B.C. was 4,800/cu. mm. (neutrophils 62%, lymphocytes 31%, monocytes 7%). Bronchoscopy showed the bronchial mucosa to be pale and oedematous, and biopsy revealed normal histology. Skin allergy tests showed a positive reaction to moulds (including *A. fumigatus*), negative to mushrooms. Serum precipitin tests for moulds (including *A. fumigatus*) were negative. Cultures of specimens of the compost, the casing (peat and chalk), and sweepings of dust from the floor of the mushroom sheds all grew *A. fumigatus.* The serum precipitin test against *A. fumigatus* was negative.

The circumstantial evidence was strong enough to justify advising the girl to change her occupation. When seen six months later she had lost all her former symptoms. In April 1967 she was followed up, and was found to be quite fit; a chest radiograph appeared to be normal, and the serum precipitin test was negative to *T. polyspora.*

Discussion

In all four cases there was a definite occupational history of exposure to one of the mushroom-growing processes, the first three being definitely related to spawning. Usually some hours after exposure the initial symptoms of pyrexia, headache, dizziness, nausea, vomiting, or generalized muscle aches gave way to symptoms of acute respiratory distress, with cough, chest pain, dyspnoea, but not asthmatic wheezing. The radiological appearance of diffuse mottling seen in three of the cases could be easily confused with, for example, tuberculosis or sarcoidosis. In none of the cases was there a family or previous personal history of allergic illness, and skin tests were negative, with the exception of one case, which showed a positive test to moulds (including *A. fumigatus*). There was no eosinophilia. The symptoms cleared spontaneously on removal from the environment of the mushroom farm, but some degree of residual chest tightness persisted in two cases. A corticosteroid helped the symptoms of one case to clear. In two of the four cases the serum gave positive precipitin reactions to the actinomycetes *T. polyspora* or *M. vulgaris* respectively. In the other two cases the serological precipitin tests were not carried out at the time of the original illness but some years later, by which time the precipitin antibodies may well have disappeared.

Nature of Mushroom-worker's Lung

Respiratory disorders due to dusts of vegetable fibre origin were first described by Ramazzini (1700) in flaxworkers in Italy. Since then many similar conditions have been recognized, the best known being byssinosis from cotton, and bagassosis from sugar cane. The condition called farmer's lung was first described by Campbell (1932) in Westmorland. In recent years farmer's lung has come to be recognized as a not infrequent condition occurring in agricultural workers exposed to the dust arising from disturbing mouldy hay and other vegetable matter, and to be due to hypersensitivity to an antigen present in the dust of mouldy hay. The exact nature of this antigen was for long a subject of speculation, but the work of Pepys *et al.* (1963) showed that the antigens involved were the spores of thermophilic actinomycetes growing in the heated hay, chiefly *T. polyspora,* and rarely *M. vulgaris*. By means of agar-gel diffusion and immunoelectrophoresis it was demonstrated that the serum of the majority of patients suffering from farmer's lung contained precipitins to these organisms. In farmer's lung the subject develops constitutional and respiratory symptoms, usually three to six hours after exposure to the offending dust. The symptoms are unlike those of bronchial asthma ; thus there is no wheeze, there is no eosinophilia, skin allergy tests are negative, chest radiographs show a diffuse miliary mottling, pulmonary function tests demonstrate an "alveolar block" diffusion defect, and lung biopsy reveals granulomata resembling those of sarcoidosis (Dickie and Rankin, 1958).

The clinical and radiological features of the first three cases described above certainly bear a close resemblance to those seen in farmer's lung. The finding of precipitin antibodies in two of the four cases provides the final evidence that mushroom-worker's lung is merely a variant of farmer's lung. The heating of the compost to 60° C. favours the growth of the thermophilic actinomycetes, and the inhalation of their spores provides the antigenic stimulus for the sensitization process responsible for the symptoms of mushroom-worker's lung.

Other factors which might possibly have been concerned in the aetiology of mushroom-worker's lung may be considered. Sensitivity to the mushrooms themselves or their spores does not appear to be the cause. Though *A. fumigatus* was demonstrated in the dust from the mushroom sheds there was no evidence that inhalation of these contaminant spores was responsible for the respiratory symptoms in the four cases described above. These symptoms do not seem to be due to allergy to any of the pests or insects which plague the mushrooms. For example, the mushroom fly, *Aphiochaeta agaraci,* may produce a specific allergic asthma (Kern, 1938 ; Truitt, 1951), but this is a different condition from that described in the present paper. Nor can the fungicides or pesticides be held responsible.

Nitrogen dioxide emanating from the disturbed compost was suggested as a possible cause of mushroom-worker's lung by Bringhurst *et al.* (1959), as the condition was thought to bear a resemblance to silo-filler's disease. In silo-filler's disease (Delaney *et al.,* 1956 ; Lowry and Schuman, 1956) workers are overcome by the poisonous fumes of nitrogen dioxide arising from chemical changes in the decomposing grain stored in the silos. There is, however, no evidence that in the mushroom-growing process any significant concentration of nitrogen dioxide is produced which would be responsible for the symptoms of mushroom-worker's lung as described here.

Conclusion

It is not claimed that respiratory disorders are very common among workers at mushroom farms. Nevertheless, certain individuals do become sensitized to the organic dust containing actinomycetes arising from the compost in which the mushrooms are grown. Dust is liberated when the compost is disturbed, as in the spawning process or on emptying the mushroom sheds and trays. Every precaution should be taken to ensure that workers potentially exposed to these dusts are protected from them, either by personal masks being worn or by efficient ventilation being maintained. A rapid "cool down" after pasteurizing of the compost may also impede the growth of the offending actinomycetes.

Summary

Four cases are described of workers at mushroom-growing farms in Sussex who developed respiratory symptoms resembling those seen in farmer's lung. Chest radiographs in three showed a diffuse miliary mottling, which cleared on removal from the environment of the farm. The serum of one case contained precipitins to *Thermopolyspora polyspora,* and the serum of another case contained precipitins to *Micromonospora vulgaris*. Thermophilic actinomycetes play an important part in the causation of farmer's lung. The process of composting in mushroom-growing farms favours the growth of these thermophilic actinomycetes, and the inhalation of their spores is responsible for sensitizing certain mushroom workers and producing the condition described here as mushroom-worker's lung.

I am grateful to Dr. R. Pillman and Dr. E. C. T. Evans for allowing me to quote Cases 2 and 3. The serum precipitin tests were carried out in the laboratories of the London School of Hygiene and Tropical Medicine and the Brompton Hospital.

Dietary Iron and Haematological Status in Normal Subjects

R. H. DAVIS,* D.M.; A. JACOBS,† M.D., M.C.PATH.; ROSA RIVLIN,‡ M.R.C.S., L.R.C.P.

Brit. med. J., 1967, 3, 711–712

The maintenance of optimal haemoglobin concentration and red cell indices depends on an adequate supply of the nutrients necessary for haemopoiesis. The availability of iron depends on a positive balance between intestinal absorption and loss from the body. Iron deficiency is a common cause of anaemia (Kilpatrick, 1961) and in women is often associated with high levels of menstrual blood loss (Jacobs and Butler, 1965). When menstrual loss is increased iron balance must be maintained either by a diet with a high iron content or by an increase in the proportion absorbed by the intestine. Iron deficiency in men is most often associated with gastrointestinal blood loss and the same compensating mechanisms are necessary to maintain a normal haematological status. The relative importance of dietary iron content and increase in absorption for maintaining normal iron balance is not clear. The present study of apparently healthy individuals in a general practice shows that iron-deficiency anaemia may occur in subjects with a wide range of dietary iron intake.

Methods

Eighty-seven men and 100 women aged 20–69 were studied. They were healthy persons selected by a random process from a general practice population of approximately 7,000. The group consisted of approximately equal numbers in each 10-year age group and contained representatives of all the social classes. In men aged 20–29 years, and occasionally at other ages, it was sometimes necessary to add substitutes as their type of employment precluded an accurate dietary survey. One man completed the dietary survey but refused to allow a sample of blood to be taken. Two women were found to have a raised blood urea and their results have been excluded. In a few cases an inadequate blood sample did not allow all the haematological investigations to be completed. Each individual completed a prospective dietary survey covering seven consecutive days closely following the method described by Thomson (1958). All the food and drink consumed was weighed and recorded. The iron content of the diet was calculated by reference to the food tables of McCance and Widdowson (1960) and from data obtained from food manufacturers. Some food items were assayed by the Cardiff Public Analysts laboratory. The mean iron intake over seven days was calculated.

Before each individual survey was started the subject was visited, supplied with scales, and the procedure explained. A brief medical history was taken and an estimate for the weekly food budget obtained. The subject was also asked to supply an average daily menu. This information provided some check upon the accuracy of the weighed food items recorded. At least two additional visits were made during the survey in order to assess the standard of record-keeping. During the period of the survey a specimen of venous blood was taken either before breakfast or between midday and lunchtime. Standard haematological methods were used (Dacie and Lewis, 1963). Serum iron and iron-binding capacity was measured by the method of Ramsay (1957).

Results

Dietary iron intake in men was 8–27 mg./day (mean 17.52 ±0.47 mg.) and in women 6–24 mg./day (mean 14.10±0.34 mg.), a significant difference ($P<0.001$). Haematological values are shown in the Table. In both sexes there is a complete lack of correlation between the dietary iron intake and haemoglobin concentration, M.C.H.C., serum iron, total iron-binding capacity, and transferrin saturation. Daily iron intake and haemoglobin concentration for women is shown in the Chart. Haemoglobin concentration was below 12 g./100 ml. in 10 women and below 12.5g./100 ml. in one man. Nine of the anaemic women had not reached the menopause. Transferrin saturation was less than 16% in 11 women but in none of the men. The mean haemoglobin concentration of women aged 20–44 years (12.70±0.145 g./100 ml.) was lower than that of women aged 45–69 (13.30±0.049 g./100 ml.) ($P<0.001$). There was no significant difference in dietary iron intake between the younger women (13.96±0.037 mg./day) and the older women (14.25±0.185 mg./day). Fifty-seven of all the women for whom data are available were premenopausal and nine of these were anaemic. Forty-one women were postmenopausal and only one of these was anaemic.

Haematological Values in General Practice Patients

		No. of Cases	Range	Mean	S.E.
Haemoglobin (g./100 ml.)	Men	80	10·0–17·1	14·95	0·125
	Women	98	8·6–15·1	12·98	0·109
M.C.H.C. (%)	Men	80	30–36	33·61	0·151
	Women	98	27–36	32·31	0·143
Serum iron (µg./100 ml.)	Men	81	55–185	107·5	2·95
	Women	97	36–220	108·2	4·09
Serum iron-binding capacity (µg./100 ml.)	Men	73	210–600	326·2	3·0
	Women	88	250–492	359·2	6·4
Transferrin saturation (%)	Men	73	16·7–66·7	33·4	1·2
	Women	88	5·8–55·0	30·5	1·3

Discussion

The average daily dietary iron recorded in the present group of subjects is slightly higher than that of 14.1 mg. recorded by the National Food Survey (1966). This iron intake compares favourably with the recommendation of 12 mg. daily for adults over the age of 20 years made by the British Medical Association (1950) and would be adequate to sustain a daily iron loss from the body of 1.4 mg., assuming 10% iron absorption from food. Nineteen out of the 98 women in this survey had a daily iron intake of less than 12 mg. but the proportion of these with a haemoglobin concentration less than 12 g./100 ml. is not significantly greater than in those with a daily intake of 12 mg. or over. The Chart shows that anaemia can occur in women with different levels of dietary iron.

Normal blood values can be maintained in the presence of low iron intake only by an increase in absorption, and this presupposes that the food iron is in an available form. Absorption of ionizable iron is increased in response to anaemia except in some patients in whom achlorhydria is a limiting factor. Iron in meat and bread, which together provide 44% of the dietary iron (National Food Survey, 1966), also show this phenomenon, though not to the same degree as fully ionized iron (Hussain, Walker, Layrisse, Clark, and Finch, 1965). Elwood (1963) has shown that the iron normally added to white flour is very poorly utilized. The present data suggest that the iron content of food is not a limiting factor in maintaining iron balance in normal individuals, and it must be assumed that a considerable increase in absorption from dietary sources is possible under the stimulus of iron deficiency. The total amount of iron in the diet may be more important at levels of intake below 6 mg. daily and in individuals with impaired absorption.

Dietary iron intake and haemoglobin concentration in healthy women aged 20–69 years.

Mean iron intake and haemoglobin levels are both higher in men than in women, but there is no correlation between these two factors in either sex. In women anaemia is almost entirely confined to those still menstruating. Though haemoglobin levels are significantly lower under the age of 45 years there is no significant difference in iron intake between the younger and older women. These findings suggest that dietary iron intake may be a less important factor than menstrual blood loss in the aetiology of iron deficiency in women. They are in keeping with the observation of Hallberg, Hogdahl, Nilsson, and Rybo (1966) that there is a fall in haemoglobin concentration in women when menstrual loss exceeds 80 ml. (equal to 1.2 mg. of iron daily) and a fall in serum iron level when it exceeds 60 ml. (equal to 1 mg. of iron daily). Garby (1966) states that only a few individuals are in negative iron balance on a daily intake of 10–13 mg. It seems likely that in a normal population iron loss from the body is the most important determinant of iron status and that dietary iron is only limiting at very low levels or in individuals with a high iron loss.

Summary

A dietary survey in apparently healthy subjects showed no relation between iron intake and haematological status. It is suggested that iron loss from the body rather than dietary iron intake is the major determinant of iron status in normal individuals.

We should like to thank Professor H. Scarborough for his encouragement and the Medical Council for a grant to R.H.D.

Acro-osteolysis Occurring in Men Engaged in the Polymerization of Vinyl Chloride

D. KENWIN HARRIS,* M.B., B.S.; W. G. F. ADAMS,† M.B., CH.B.

[WITH SPECIAL PLATE BETWEEN PAGES 708 AND 709]

Brit. med. J., 1967, **3**, 712–714

The polymerization of vinyl chloride has been undertaken in this and other countries for over 20 years without apparent harm to the workers, apart from some accidental exposure to the vapour of vinyl chloride, the anaesthetic effects of which have been well known for years. The process consists, briefly, in submitting a mixture of liquid vinyl chloride and water in the presence of a catalyst to the effects of heat in large pressure vessels known as autoclaves. This produces polyvinyl chloride in slurry or latex form which is discharged from the vessel and conveyed elsewhere to be dried into a powder. When the autoclave is emptied at this final stage a deposit of white polymer is found on its inner wall. Air is then blown through the open vessel for at least a quarter of an hour, after which an atmosphere test for vinyl chloride is done inside it. If the autoclave is found to be clear of vinyl chloride vapour the cleaner enters it to scrape the wall with a small hand pallet.

An unusual condition affecting two men employed as autoclave cleaners in this process was first reported by Cordier *et al.* (1966). After doing this work for several months they developed symptoms resembling those of Raynaud's phenomenon and later a skin eruption of the hands, and in one case of the forearms, together with general asthenia and drowsiness. The most striking sign, however, was the radiological evidence of lysis of some terminal phalanges of the hands, and in one case of the feet. Most of these abnormalities disappeared and the bones showed signs of healing a year or two after the men had stopped work.

In view of that article, the hands of 588 men engaged in the manufacture of polyvinyl chloride were radiographed in

† Imperial Chemical Industries Limited, Mond Division.

April 1966; 150 of them were autoclave cleaners. Two cases with *x*-ray changes in the fingers similar to those described by Cordier *et al.* (1966) were found.

Case 1

A 44-year-old man who had worked on the autoclave section of the plant since 1950 had an interesting history in that he was diagnosed as a case of scleroderma by a consultant physician and dermatologist in 1957. The diagnosis was made on clinical grounds because of Raynaud's phenomenon, accompanied by puffiness of the face and thickening of the skin of the hands, fingers, and left forearm. The symptoms cannot have been very troublesome, because he had made no complaint, and the condition was noticed by his doctor only when he went to collect a prescription for his wife.

On being questioned about his condition during the present investigation he still made no complaints, and it was only with reticence that he admitted that his hands often felt unduly cold.

Examination revealed no evidence of the skin condition that had existed in 1957, and the only abnormalities were: (*a*) pseudoclubbing of all the fingers of both hands; this is not true clubbing, since the angle between the base of the nail and the adjacent skin was not obliterated; and (*b*) the liver was palpable on inspiration.

Radiological Reports.—"*Hands*: Periarticular erosions are present in the proximal interphalangeal joints. The proximal interphalangeal joint of the left little finger is disorganized. There are erosions of the terminal phalanges of index and middle fingers of both hands (Special Plate, Fig. 1). *Feet*: The fifth proximal phalanges of both feet show erosions on both their distal ends. The fifth proximal interphalangeal joint is disorganized on the left (Special Plate, Fig. 2). *Pelvis*: There is a widening of the joint space of the sacroiliac joint with cystic marginal sclerosis. *Chest*: Normal. *Skull*: Normal. *Cervical spine*: Normal. *Teeth*: Normal. *E.C.G.*: Normal."

Laboratory tests were carried out, and the only abnormality found was a persistently raised serum bilirubin.

Case 2

A 30-year-old man who had been an autoclave cleaner since 1960, having been self-employed as a window-cleaner before that date, recalled no previous serious illness, but had consulted his doctor in 1964 because of shortening of his finger-nails, which he thought to be due to biting them and "lack of calcium."

In April 1966 he had no symptoms, but radiologically he showed evidence of acro-osteolysis. Pseudoclubbing of the fingers was found to be present (Fig. I). Raised nodules in the skin, described as "xanthomatous-like" patches, were noted round his wrists.

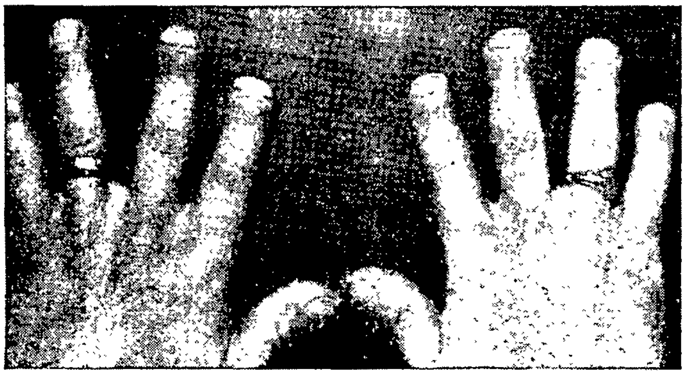

FIG. I.—Pseudoclubbing of the fingers.

Radiological Reports.—"*Hands*: Osteolysis is present in the shafts of all the terminal phalanges of the fingers and thumb, with the exception of the left ring finger" (Special Plate, Fig. 3). (Incidentally it is of interest to note that in most of the *x*-ray films of these cases seen by us here and in America the ring finger is unaffected.) "*Sacrum*: Widening of the joint spaces of the sacroiliac joint with cystic marginal sclerosis (Special Plate, Fig. 5). *Chest*: Normal."

The most notable feature was the comparative absence of abnormal findings, apart from those shown on the *x*-ray films. Laboratory tests showed nothing abnormal.

In July, however, he came to see one of us (W. G. F. A.) complaining of fairly persistent pain and frequent attacks of coldness in the fingers, accompanied by pallor. On examination at this time there was some tenderness of the finger-tips, more skin nodules were seen to be developing on the dorsum of his fingers, and some thickening and coarsening of the skin of the face was noted.

In the course of the next week or two the pains in the fingers and metacarpophalangeal joints increased, and Raynaud's phenomenon was troublesome even in warm weather. He was therefore admitted to hospital in August for further investigation.

The same tests as on the previous occasion were repeated, and once again the results were within normal limits, except in the case of the serum proteins. In this test the serum α2-globulin was 1 mg./100 ml. (normal 0.4–0.8 mg.). Hyland screening tests for rheumatoid arthritis and lupus erythematosus were normal. Serum transaminase was within normal limits. The E.S.R. had fallen to 4 mm. in one hour (Westergren). Blood pressure was 140/80.

Skin biopsy was performed on one of the nodules on the wrist, the histological report being as follows: "The full thickness of the dermis is incorporated in an interlacing acellular collagenous nodule, oedematous and partly hyalinized, enclosing normal sweat glands and covered by normal epidermis (Fig. II). The oedematous interstices contain a fine granular and filamentous material, metachromatic with toluidine blue, and staining faintly with alcian blue and periodic-acid Schiff, probably breaking up elastic (Fig. III). Two small dermal arteries are extremely thick-walled as a result of marked medial hypertrophy and intimal fibrous

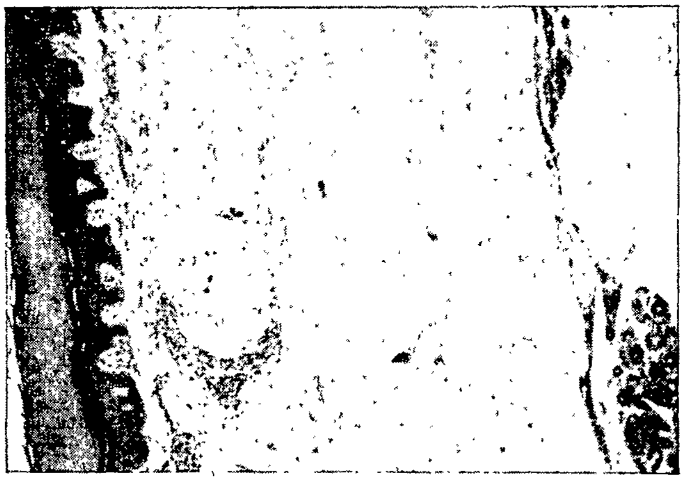

FIG. II.—Case 2. General appearance of thickened dermal collagen—also showing lymphocytic cuffing of small dermal blood vessel. (H. and E. ×55.)

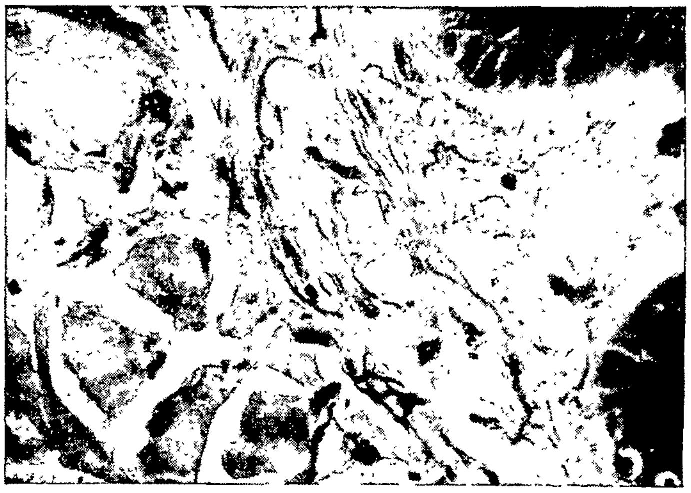

FIG. III.—Case 2. High-power view of fragmented elastic in upper dermis. (Verhoeff. ×270.)

thickening (Fig. IV). The appearances are similar to those described by Cordier *et al.* (1966)."

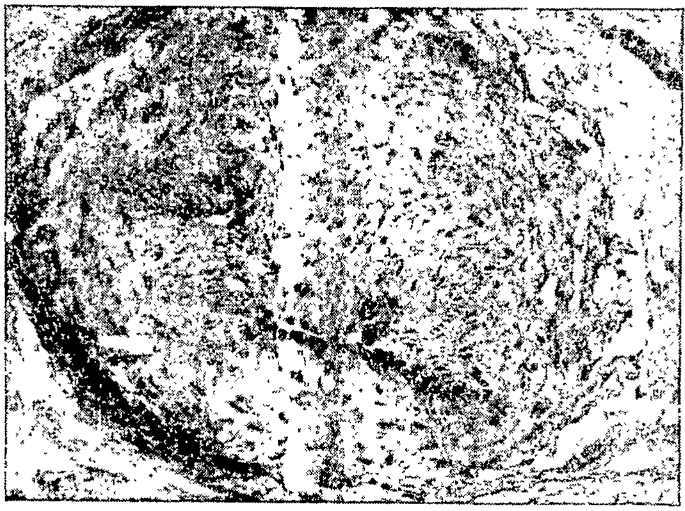

FIG. IV.—Case 2. High-power view of artery situated deeply within the zone of thickened dermal collagen. (H. and E. ×180.)

For a few months after his discharge from hospital he improved, and by the end of 1966 the Raynaud's phenomenon was less marked and the skin nodules were disappearing. About this time, however, he began to develop pain in the left knee and toes. *X*-ray examination of the left knee showed a cortical erosion on the posterior surface of the patella (Special Plate, Fig. 4). By June 1967 he felt reasonably well, though he still complained of pain in the left knee and stiffness of the hands, particularly at the metacarpophalangeal joints. The skin of the hands and face was practically normal.

Comment

No treatment was required in Case 1, and the treatment in Case 2 was directed towards relieving the symptoms, since no specific remedy is known for the condition.

Both men were removed from the job of autoclave cleaning as soon as the diagnosis was made, but it is not yet certain how this measure will affect the course of the illness. It would appear that Case 1 went through the acute stage while still doing his normal job, and the condition has become quiescent in spite of this.

Two more possible cases were found in our most recent survey. One of these is a 30-year-old autoclave cleaner who has had Raynaud's phenomenon for three years, but in whom no bony changes have been found. The other man is an ex-autoclave-cleaner in whom a suspicious appearance has been noted radiologically in the right thumb, which had, however, been recently subjected to injury.

Discussion

In view of the similarity of the findings in these men to the cases described in the paper of Cordier *et al.* (1966), it was thought that this condition was almost certainly linked with the men's occupation. Inquiries subsequently made in America and Europe revealed that similar cases had occurred there. In all cases the features appearing most consistently were Raynaud's phenomenon accompanied by osteolysis of the terminal phalanges of the fingers, occurring mainly in autoclave cleaners and not in those engaged in handling the finished product.

Many raw materials may be used in small quantities in manufacturing the polymer, but the only substance common to all cases is probably vinyl chloride. Though every autoclave is washed with water and has air blown through it at the end of each reaction, small quantities of vinyl chloride may remain and escape when the vessel lid is opened. It is also possible that very small pockets of gas may be trapped beneath the polymer adhering to the inner wall, and these can be liberated during the subsequent cleaning process. Vinyl chloride, however, has been manufactured and handled in this country for over 20 years without apparent harm apart from accidental exposure to its well-known anaesthetic action.

A point of general interest is the possible relationship of this condition to the collagen diseases. One patient (Case 1) had, in fact, been diagnosed as a case of scleroderma on clinical grounds 10 years previously. The histologist remarked on the superficial similarity of the biopsy taken in Case 2 to scleroderma, but a number of pathologists consider the appearance of the section to be unique. Cordier *et al.* (1966) mention an unusual skin condition seen in their cases. Suciu *et al.* (1963), in a paper describing conditions produced by vinyl chloride, referred to a skin lesion resembling scleroderma, but acro-osteolysis was not mentioned.

Finally, at a clinicopathological conference at the Royal Postgraduate Medical School (*B.M.J.*, 1966) it was stated that bony changes were commonly found in the terminal phalanges in scleroderma. It should be made quite clear, however, that the many radiologists who have looked at the films of our cases stated that they had not previously seen this particular lesion.

It would appear from our own and other cases that this condition is probably a self-limiting disease, which in spite of bone destruction leaves the patient with little disability. In *x*-ray films taken a year after the original diagnosis no further bony changes were noted in Case 1. In Case 2, however, there was evidence of partial ossification of the osteolytic bands in the terminal phalanges of both hands.

It is our intention to continue annual radiological examination of the hands of all men engaged on this work. Mechanical methods of cleaning new autoclaves have been introduced, and it is hoped in due course to extend this method to older vessels and thus eliminate the human factor.

Summary

Two cases of acro-osteolysis occurring in men engaged in the polymerization of vinyl chloride are described. The bones affected were the terminal phalanges of the fingers and the sacroiliac joints, but in one case the patella and in the other the phalanges of the feet were involved. The condition was accompanied by Raynaud's phenomenon and skin lesions.

It would seem that this condition is probably a self-limiting disease.

We acknowledge with gratitude the help given throughout this investigation by Dr. Thelwall Jones and other members of the medical staff of the David Lewis Northern Hospital, Liverpool, and by Dr. K. A. Rowley and his colleagues at Blackpool Victoria Hospital.

Sickle-cell Haemoglobin O Disease in a Sudanese Family

S. A. IBRAHIM,* D.K.S.M., PH.D.; DAOUD MUSTAFA,† D.K.S.M., F.R.C.P.

Brit. med. J., 1967, 3, 715–717

Besides sickle-cell anaemia, the finding of Hb S with other β-chain variants of adult haemoglobin was first demonstrated by Itano and Neel (1950) in the well-known discovery of sickle-cell Hb C disease. Since then Hb S has been observed with Hb D, E, G, J, and K (Itano, 1951; Aksoy and Lehmann, 1957; Schwartz and Spaet, 1955; Went and MacIver, 1959; O'Gorman *et al.*, 1963). In such circumstances there is a sickle-cell disease which, while of varying severity, is milder than the homozygous sickle-cell anaemia.

Hb S was first observed with Hb O in two children of an Arab family who were reported to be suffering from a sickle-cell Hb O trait condition. In those cases some Hb A was also found in addition to Hb S and O (Ramot *et al.*, 1960), and it was subsequently concluded that there must have been a previous blood transfusion (Baglioni and Lehmann, 1962). The clinical picture of sickle-cell Hb O disease has not yet been reported. The present report describes two cases which occurred in a Sudanese family.

Case 1

A Sudanese man aged 27 coming from the village of Abu Haraz, Gezira, was admitted into Khartoum Hospital on 1 September 1966 complaining of joint pains and malaise for one month and fever for seven days. Since early childhood he had suffered from similar attacks with occasional episodes of jaundice, which were often precipitated by exertion. During infancy he had bouts of screaming, and was once taken to a native healer, who manipulated the patient's upper limbs. It was thought that as a result of such manipulations he developed severe tenderness and swelling of the left shoulder. The swelling was later incised and pus was drained. The patient had had the last attack of joint pains about a month previously when he was admitted to a district hospital, and it was while there that severe pain developed, with swelling of the right shoulder. The condition was diagnosed as rheumatoid arthritis and he was given salicylates and corticosteroids without benefit. The pain and swelling in the right shoulder persisted till his admission into Khartoum Hospital. Four months previously he had been found to have intestinal schistosomiasis and was treated with stibophen (Fouadin).

On admission he was ill-looking, in pain, wasted, and anaemic but not jaundiced. He had a large skull and was running a temperature of 103° F. (39.4° C.). Heart, lungs, and abdomen were normal; liver and spleen were not palpable. He had brisk tendon reflexes, but otherwise the nervous system was normal. The fundus oculi showed slight engorgement of the retinal veins and arteriovenous nipping. The right shoulder was swollen, hot, and tender, with induration of the overlying deltoid and adjacent pectoralis major. Movements were restricted on account of pain. The left arm was smaller and 8 cm. shorter than the right.

TABLE I.—*Haematological Findings in Two Patients Suffering from Sickle-cell Hb O Disease*

Case No.	Age in Years	Sickling Test	Adult Haemoglobins	Hb F (%)	Haemoglobin (g./100 ml.)	P.C.V. (%)	M.C.H.C. (%)	Reticulocytes (%)
1	27	+	S+O	5·5	8·5	28	34	0·8
2	15	+	S+O	4·5	9	29	31	18

Investigations.—The haematological findings are given in Table I. A peripheral blood film showed many target cells, a few sickle cells, and some normoblasts. The erythrocytes showed anisocytosis and poikilocytosis. No malaria parasites were seen. Total W.B.C. 6,400/cu. mm. (polymorphs 61%, lymphocytes 35%, eosinophils 2%, and monocytes 2%). Bone marrow was predominantly normo-

blastic with a fair number of megaloblasts and an increase of plasma cells. The blood chemistry is shown in Table II. Urine contained an excessive amount of urobilinogen, a trace of protein, but no R.B.C.s or bilirubin. Stools were repeatedly negative for schistosome ova. Haemoglobin electrophoresis showed Hb S+O (Fig. 1). This finding was confirmed by Dr. H. Lehmann at the M.R.C. Abnormal Haemoglobin Research Unit, Cambridge. Hb F constituted 5.5% of total haemoglobin. Electrophoresis of serum, using barbitone buffer, revealed a marked increase in the γ-globulin fraction. *X*-ray examination showed osteoporosis of the head of the right humerus, thinning of the cortex, and periosteal reaction in the humeral neck (Fig. 2). The skull was osteoporotic with opacities, and had a hair-on-end appearance. The left humerus was small, short, and had a very small remnant of a head (Fig. 3).

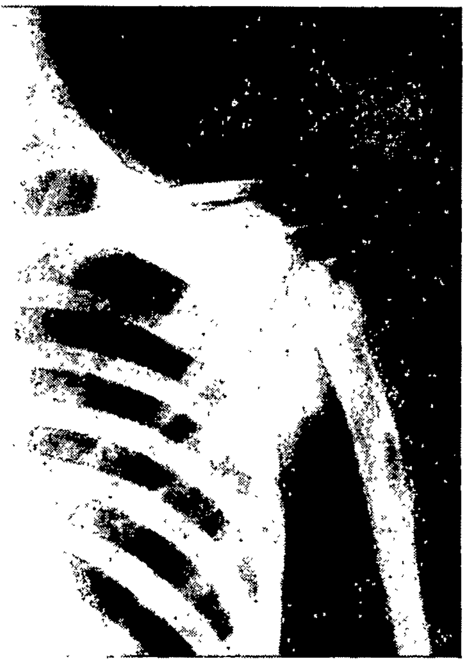

FIG. 3.—Case 1. *X*-ray film of left shoulder, showing a small remnant of left humeral head, thinning of cortex, and periosteal reaction in the shaft.

He ran a temperature of up to 102° F. (38.9° C.) for three weeks. The swelling in the right shoulder improved very slowly. On 25 October he complained of severe pain in the left loin and had microscopic haematuria, which cleared up in about a week. On 30 October a painful swelling appeared in the middle of his left femur which subsided in about a week. On 1 December the right shoulder swelling and pain got much worse. He was put on folic acid tablets, and this converted the marrow to normoblastic and resulted in haematological improvement.

Case 2

A Sudanese girl aged 15, sister of Case 1, was admitted to hospital on 1 October 1966, having had jaundice for two months, fever and cough for one month, and a painful swelling of the left shoulder for 10 days.

Since early childhood she had suffered from attacks of joint pains sometimes associated with swellings. At the age of 3 years she had a severe attack of measles accompanied by a painful swelling of both hands, including the fingers. Since then some fingers were noted to have become shorter. At the age of 6 she had jaundice, which lasted for one month.

On admission she had a temperature of 100° F. (37.8° C.) and was looking very ill, wasted, anaemic, and mildly jaundiced. Pulse was collapsing; B.P. 100/60; apex beat was in fourth space at the midclavicular line. No murmurs were heard. There were signs of right lower lobar pneumonia, and tender bony swellings were present on the seventh and eighth right ribs and on the sixth, eighth, and ninth left ribs at the midaxillary line. Liver and spleen were not palpable. Besides brisk tendon reflexes, the nervous system was normal. There was a moderately swollen left shoulder, which was hot and tender. The right middle finger was short and the proximal interphalangeal joint of the left index was ankylosed.

Investigations.—The haematological findings were as follows. A peripheral blood smear with many target cells, a few sickle cells, and erythrocytes showing anisocytosis and poikilocytosis. No malaria parasites were seen. Total W.B.C. 10,300/cu. mm. (polymorphs 69%, lymphocytes 24%, monocytes 5% and metamyelocytes 2%). The bone marrow was hyperactive, predominantly normoblastic, with a fair number of megaloblasts and an increase in plasma cells. E.S.R. 7 mm. in the first hour (Westergren). Serum calcium was 9.9 mg./100 ml. and phosphorus 3.8 mg./100 ml. The rest of the blood chemistry is shown in Table II. The urine contained a fair number of erythrocytes, urobilinogen in excess, but no bilirubin. Stools were normal. Electrophoresis of the haemoglobin revealed Hb S+O, a finding that was confirmed by Dr. H. Lehmann. Hb F constituted 4.5% of the total haemoglobin. Electrophoresis of serum showed a considerable increase in the γ-globulin fraction. *X*-ray examination of the chest showed right lower zone opacity and small areas of bone destruction in the right eighth and ninth ribs and to a less extent in the left sixth and eighth ribs at the sites corresponding to the tender swellings seen externally. An *x*-ray film of both hands (Fig. 4) showed that with the exception of the thumb the fingers of the left hand were all shorter than normal owing to reduction of the proximal and middle phalanges. The proximal phalanx of the right middle finger was also short. The ends of the affected phalanges showed osteoporosis, with cupping at the metacarpophalangeal and interphalangeal joints and reduction of joint spaces.

The patient maintained a low-grade fever for three weeks. The pneumonia and rib swellings subsided gradually. On 15 October she developed a painful swelling over the right radius; this subsided in a few days. On 8 November the old rib swellings subsided but two new non-tender swellings of the right eighth and ninth ribs appeared in the scapular line. On 30 November the left shoulder swelling and pain became worse. She was put on folic acid, and this converted the marrow to normoblastic with haematological improvement.

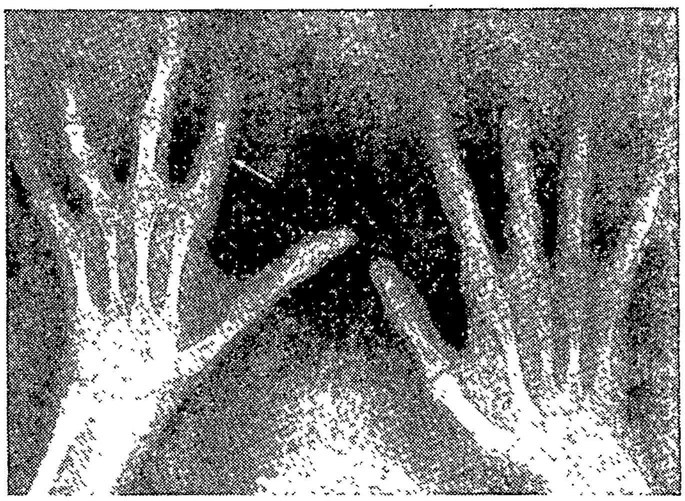

FIG. 4.—Case 2. *X*-ray film of both hands, showing shortening of the proximal and middle phalanges, osteoporosis, and cupping at the joints of the affected fingers. The proximal interphalangeal joint of the left index is ankylosed.

Family History

The parents are distant cousins; both are alive and well. They have eight more siblings—five daughters and three sons—who are reported to be well. One child died four days after birth.

Electrophoresis of haemoglobin showed that the father has Hb A+S while the mother has Hb A+O (see Fig. 1). The rest of the family have not yet been examined.

Discussion

The incidence of Hb S and O Arab in Northern Sudanese has been reported as 2 and 0.1% respectively (Vella *et al.*, 1966).

Examination of the peptides arising from tryptic digestion of the abnormal haemoglobin has shown that haemoglobin O Arab harbours the chemical abnormality in the β-polypeptide chains of the molecule (Baglioni and Lehmann, 1962). It has also been shown that Hb S differs from Hb A in the amino-acid composition of the β-polypeptide chains (Ingram, 1959). Since adult haemoglobins are genetically determined by allelomorphic genes inherited in a Mendelian fashion, then the inheritance of the genes for Hb S and O by an individual will result in the formation of only Hb S+O by that individual. No Hb A will therefore be formed, since the genes for Hb S and O both produce haemoglobins which are abnormal in the β-chains.

The clinical picture of sickle-cell Hb O disease has hitherto not been described. Both patients whose cases are reported here are Northern Sudanese of Arab ancestry in whom the onset of symptoms of the disease began early in life. The bony lesion of the left shoulder in Case 1 and of both hands in Case 2 are probably manifestations that had taken place in infancy and early childhood respectively. The onset of symptoms in sickle-cell disease is generally later than in sickle-cell anaemia, though it has been reported that in about 80% of the cases of SC disease the symptoms began in the first decade of life (Hook and Cooper, 1958).

The most prominent clinical features in these two cases of SO disease are the joint pains and bony lesions involving humeri, ribs, skull, hands, femur, and radius, and of particular prominence is the marked affliction of the head of the humerus. Aseptic necroses of the femoral and humeral epiphyses are very common in SC disease (Smith and Conley, 1954 ; Hook and Cooper, 1958 ; Ranney, 1958). Burchmore *et al.* (1962) suggested that arterial occlusion rather than capillary obstruction may be the main factor in the production of avascular necroses, multiple infarcts, and painful swellings seen in SC disease. Indeed, these authors provided unequivocal evidence of arterial occlusion in the case they reported.

Another prominent feature in our cases is the marked decrease of plasma albumin along with the considerable increase in γ-globulin. The common diseases which cause such a disturbance of plasma proteins in the Sudan are leishmaniasis, hepatosplenic schistosomiasis, chronic malaria, and hepatic cirrhosis. These two patients were not suffering from leishmaniasis and there was no evidence of chronic malaria. Though Case 1 gave a history of intestinal schistosomiasis for which he received treatment there was no clinical evidence of hepatosplenic involvement. Liver disease and disturbed liver function have been described in cases of sickle-cell anaemia. Thus decreased plasma albumin and increased γ-globulin were reported by Fenichel *et al.* (1950). Histological evidence of liver disease, together with disturbance in plasma proteins and liver function tests, was also given by Green *et al.* (1953). In the case of SC disease described by Burchmore *et al.* (1962) a considerable increase in the γ-globulin was also reported. It would seem probable that the disturbances in plasma proteins seen in our patients were due to hepatic disease. In both cases there was an increase in plasma cells in the bone marrow. Patients with liver disease who have very high serum globulin show plasmocytosis of the bone marrow (Sherlock, 1963).

In neither of our cases was there a palpable spleen. Splenomegaly occurs in the majority of cases of SC disease, in contrast to sickle-cell anaemia, in which a palpable spleen is detected in only a small proportion of cases (Wintrobe, 1961). However, Edington (1957) reported that in some cases of SC disease the spleen may be fibrosed and hence cannot be felt.

Though in both cases the anaemia has been severe, it is fairly well tolerated. Both had megaloblastic erythropoiesis. Haemolytic anaemia as a factor in the development of megaloblastic erythropoiesis has been demonstrated in the specific case of sickle-cell anaemia by Jonsson *et al.* (1959) and by Watson-Williams (1962). Megaloblastic anaemia complicating SC disease has been reported by Fullerton and Watson-Williams (1962), and the megaloblastosis has been attributed to excessive folic acid requirements.

It is of interest to note that one of our patients (Case 1) developed severe left loin pain which was associated with microscopic haematuria otherwise not observed in previous urine tests. Haematuria occurs in sickle-cell anaemia and in sickle-cell trait (Wintrobe, 1961). Massive haematuria that is probably the result of renal arterial occlusion (Burchmore *et al.*, 1962) often occurs in SC disease (Smith and Conley, 1954, 1958).

Summary

Two cases of a hitherto undescribed condition of sickle-cell Hb O disease are reported in detail and the relevant literature is reviewed. The prominent features of this condition (SO disease) are joint pains, bony lesions, anaemia, and marked disturbances of the plasma proteins. The occurrence of megaloblastic anaemia is also reported. Like other sickle-cell diseases, SO disease is relatively mild. The clinical picture bears some resemblance to that of SC disease.

We are grateful to Dr. H. Lehmann, Director, M.R.C. Abnormal Haemoglobin Research Unit, Cambridge, for confirming the finding of the abnormal haemoglobins and for valuable discussions while he was in Khartoum ; to Mr. T. R. Davis, Faculty of Pharmacy, Khartoum, for photographing the electrophoretograms ; to Professor K. R. Adam, of the Biochemistry Department, for advice ; and to Research Assistant Dr. El Daw Mokhtar for help.

Preliminary Communications

Intestinal Spirochaetosis

[WITH SPECIAL PLATE BETWEEN PAGES 708 AND 709]

Brit. med. J., 1967, 3, 718–719

The purpose of this paper is to draw attention to a form of intestinal spirochaetosis that does not appear to have been previously described and yet would seem to be not infrequent. The condition was first noticed while the rectal mucus membrane was being viewed through the electron microscope.

INITIAL OBSERVATIONS

The patient, a man aged 64, had complained of persistent diarrhoea for three years. A rectal biopsy was taken as part of the clinical investigation, and on light microscopy nothing of note was seen. Small fragments of this biopsy specimen were fixed in 1% osmium tetroxide in phosphate buffer at *p*H 7.4 and embedded in Araldite, and thin sections were viewed in a Siemens Elmiskop 1A electron microscope.

Clinical Features of 10 Cases of Intestinal Spirochaetosis

Case No.	Sex	Age	Complaint	Duration of Symptoms	Clinical Diagnosis
1	M	64	Diarrhoea	3 years	?
2	M	52	Mucoid diarrhoea	2–3 days	Carcinoma of colon
3	M	49	Diarrhoea	4 weeks	?
4	F	19	Abdominal pain	1½ years	Appendicitis. Haemorrhoids
5	F	64	Constipation	5 ,,	Carcinoma of colon
6	M	56	Rectal bleeding	6 months	Haemorrhoids
7	M	56	,, ,,	8 ,,	Carcinoma of colon
8	M	60	Intermittent rectal bleeding	1 year	Multiple polyps Carcinoma of colon
9	M	61	Rectal bleeding	2 years	Haemorrhoids Polyps of colon
10	M	63	Diarrhoea	2 weeks	Carcinoma of colon

The electron microscopical findings are illustrated in the Fig. (Special Plate). Adherent to the surface of the epithelium was a forest of organisms, orientated in the long axis of the cells. The organisms were short and thin and had two or three short curves. They measured up to 3 μ in length and only 0.15 μ in average diameter. They were too short and thin for bacilli. Under high magnification occasional organisms, cut tangentially, showed bunches of spiral filaments. This finding, together with the shape and size of the organisms, indicated that they were spirochaetes.

The spirochaetes sometimes penetrated short distances into the epithelial cells, pushing the plasma membrane before them. Occasionally a vacuole could be seen forming in the cytoplasm of the cell at the tip of the organism. Some of the epithelial cells appeared to have an increased number of lysosomes, but no other reaction was noticed. There was no significant inflammation. Where the surface of the cells had been cut transversely each organism could be seen to be surrounded by a cluster of microvilli. This probably accounts for the consistent longitudinal orientation of the organisms.

Reappraisal of the routine histological sections in the light of the electron microscopical findings revealed a very faint blue haze on the surface of the mucosal cells.

SUBSEQUENT INVESTIGATIONS

It was soon realized that this basophil reaction had been seen histologically in other rectal biopsies but that it had been interpreted as an unusual staining of the brush border of no significance. A review of 100 consecutive rectal biopsies from the files of this department was then undertaken. In nine cases a faint blue haze, exactly as seen in the first biopsy, was present. It was clearly necessary to find out if all of these cases represented a single entity. Small blocks of tissue were excised from the paraffin wax in which they had been stored, the wax was removed in chloroform, and the tissue was post-fixed in osmium tetroxide, after rehydration through graded alcohols. Thin sections were then examined in the electron microscope.

Preservation of the tissue was naturally poor, but in all nine cases spiral organisms identical in size and shape to those seen in the original case were readily identified. As before, they were closely applied to the surface epithelium and in some places just penetrated the cell surface.

It was concluded that all these cases represent a single pathological entity, which we have called intestinal spirochaetosis. This condition can be readily diagnosed in rectal biopsies. It is recognized histologically, even with the low-power objective, as a distinct haematoxyphilic zone occupying the site of the normal brush border. This zone is about 3μ in width. It is not possible to resolve individual organisms in routine paraffin sections because of the thickness of the sections, but individual organisms can be resolved by the light microscope in very thin (1 μ) sections prepared from Araldite-embedded material.

CLINICAL OBSERVATIONS

The main clinical features of the 10 cases are shown in the Table. Both sexes are involved and there is a wide age distribution. All patients had symptoms referable to the bowel. In five cases carcinoma of the colon was definitely diagnosed either by the first biopsy or at a later date. It is of interest that in these cases only the normal mucosa, adjacent to the cancer, was infested by spirochaetes. In three cases haemorrhoids were thought to be the cause of symptoms.

There is evidence that intestinal spirochaetosis can persist for considerable periods. In Case 2, for example, the condition was diagnosed in two biopsies taken 17 days apart, but after preoperative antibiotic treatment spirochaetes were not identified in the resection specimen. In Case 1 two biopsies were both positive ; they were separated by a period of five months, during which the patient's symptoms persisted. Case 8 had five biopsies in six years and all showed clear evidence of spirochaetosis.

Case 4 is of special interest. This patient had had attacks of abdominal pain for one and a half years which led to appendicectomy. She still had symptoms, and haemorrhoids were injected. Spirochaetosis was present not only in the rectal biopsy specimen but also in the appendix removed two months earlier.

DISCUSSION

Since the last century spirochaetes have been known to be present in the intestinal tract, but have usually been regarded as harmless commensals. However, there are scattered reports in the literature that large numbers of spirochaetes can be found in the stool of patients with various forms of dysentery and cholera (Parr, 1923). In addition there are dysentery-like diseases, associated with spirochaetes, which have responded only to treatment with arsenicals (Sáenz, 1925). It is also claimed that spirochaetes are responsible for guinea-pig diarrhoea (Sanarelli, 1927).

Presumably because they have been considered to be non-pathogenic, there has been little attempt to culture and further classify these organisms. However, the morphological descriptions of the commonest organisms, the so-called *Spirochaeta eurygyrata* (Hogue, 1922), closely resemble the spirochaete found in this group of patients. Because these organisms stain with haematoxylin, we think that they would be best classified as Borrelia. In future publications further details will be presented.

It is not possible at the present time to decide the significance of our findings. All the patients had rectal biopsies performed because of symptoms of one sort or another referable to the bowel. Some were found to be suffering from carcinoma of the colon. On the other hand, others had dysenteric symptoms of unknown cause, and these might possibly be cases of "spirochaetal dysentery." Antibiotic treatment of some of these cases may provide an answer to this problem, since we have reason to believe that the spirochaetes disappeared in one case after preoperative antibiotic therapy. There is also the possibility that this form of spirochaetosis gives rise to vague abdominal symptoms simulating appendicitis. It remains quite possible, however, that this attachment of spirochaetes to the surface of the colonic mucous membrane has no clinical significance.

SUMMARY

Ten cases of a new and apparently common form of intestinal spirochaetosis are described. The condition was first recognized by electron microscopy, but diagnosis can be made on routine histological preparations. Short spirochaetes, tentatively classified as *Borrelia eurygyrata*, are attached to and penetrate short distances into the surface epithelial cells. They are characteristically orientated in the long axis of the cells. At present it is not possible to decide the significance of our findings.

We acknowledge the invaluable technical assistance of Mr. D. McSeveney, whose skill made this study possible; we thank Mr. D. H. Clark, who referred the first patient to us; and we acknowledge the financial assistance from the M.R.C., who provided the electron microscope.

Volvulus of the Small Intestine after Herniorrhaphy

Brit. med. J., 1967, 3, 719–720

Primary volvulus of the small intestine is rare in Great Britain and its cause is usually obscure. Renton (1965) found five reported examples and added one of his own. Secondary volvulus is relatively common and its cause is better understood. The present case is reported in the hope that it may contribute to further understanding of the factors precipitating intestinal volvulus.

CASE REPORT

At 2 p.m. on 15 March 1966 a 68-year-old farmer developed lower abdominal pain after lifting a heavy weight while working in his fields. At the same time he noticed a tender swelling in his right groin. He was admitted to hospital at 6 p.m. For two years he had been aware of a small hernia in the right groin which previously had always been easily reduced. During the last seven years he had experienced attacks of abdominal distension, associated with flatulent discomfort, which lasted up to 10 days and resolved with the passage of watery diarrhoea. These attacks occurred two or three times a year and appeared to be unconnected with any disturbance in his hernia. He was not a vegetarian and ate a regular balanced diet.

On admission his general condition appeared satisfactory. His pulse was 72. The blood pressure was 160/80 mm. Hg. His chest showed signs of chronic bronchitis. A tender irreducible right inguinal hernia was present. The abdomen was not distended but bowel sounds were increased.

That evening the inguinal hernia was explored (N. H. V.) under general anaesthesia. It was found to be direct in type and to contain 6 in. (15 cm.) of gangrenous ileum, which was resected. End-to-end anastomosis was carried out and the hernia was repaired. Over the next few days his abdomen became painlessly distended and he was thought to have developed a paralytic ileus. On 19 March his bowels moved loosely and thereafter he had two or three loose motions daily, but the abdominal distension remained. He vomited 200 ml. of stomach contents on 22 March. When this was repeated on the 23rd an intravenous infusion of dextrose saline was started. On the 24th his abdomen suddenly became further distended, having increased 2 in. (5 cm.) in girth overnight. There was generalized abdominal tenderness and guarding. His pulse was 100. The blood pressure was 135/80. *X*-ray examination of the abdomen showed small-bowel distension, with fluid levels suggestive of obstruction in the distal ileum.

After the passage of an oesophageal tube and aspiration of the stomach, laparotomy was performed (C. J. C. R.). Blood-stained fluid was present in the peritoneal cavity. The small intestine was very distended, was dark purple in colour, and its viability appeared doubtful. The entire small intestine, except for the proximal 4 ft. (1.2 m.) of jejunum, had undergone a clockwise rotation of 720 degrees. There were no adhesions, and the previous anastomosis was patent and lying free in the right iliac fossa. No congenital or acquired abnormality was found to account for the volvulus. On reducing the volvulus the circulation to the intestine recovered. Because of the gross distension the bowel was deflated by a suction tube introduced through an enterotomy. The bowel was closed and the original anastomosis, which had leaked after handling, was oversewn. Later the same evening sputum retention and bronchospasm produced increasing dyspnoea, cyanosis, and carbon dioxide retention, leading to respiratory failure. Tracheostomy was performed (N. H. V.), allowing regular bronchial toilet. With physiotherapy, antispasmodics, and antibiotics respiratory function was improved. Gastric suction and intravenous infusions were continued until 28 March, when the abdominal distension started to resolve. His bowels thereafter moved once a day. Two episodes of vomiting on 2 and 6 April necessitated further gastric suction. By 8 April the vomiting and the abdominal distension had completely settled. The tracheostomy tube was removed and convalescence continued uneventfully.

COMMENT

In primary volvulus of the small intestine there is no obvious predisposing cause. It is commoner in Africa and India, where it is associated with a vegetarian diet of bulky indigestible food (Kerr and Kirkaldy-Willis, 1946 ; McWatters, 1945). Rose (1955), discussing the aetiology, mentioned hypermotility and bowel distension as exciting causes. In secondary volvulus there is usually an abnormal congenital or acquired fixation of the intestine.

In this case the past history is consistent with attacks of subacute volvulus recurring over seven years. Though no anatomical abnormality was obvious in the mesentery, a volvulus through 720 degrees suggests undue mobility and length of mesentery. This could have been the result of previous subacute attacks of volvulus or it could have predisposed to them. Bulky diets are said to cause an increase in length of bowel and mesentery as well as hypermotility (Dickson, 1950). There was no evidence of unusual dietary habits in this patient. The right inguinal hernia might have anchored a loop of small intestine and produced a secondary volvulus. However, this hernia was said to be easily reducible up to the final attack of strangulation and to have been present for only two years. If it was responsible its repair should have cured the tendency for the bowel to undergo volvulus.

The final attack of volvulus appeared to start only after the inguinal hernia had been repaired and the bowel resected. It is possible, though unlikely, that the anastomosis acted like the occasionally reported antimesenteric tumour by partly anchoring the bowel and predisposing to volvulus (Aird, 1957). Lulenski (1961) reported cases where volvulus was superimposed on small-bowel obstruction. In this case the anastomosis appeared widely patent without any evidence that it could have caused mechanical obstruction. After any abdominal operation, especially with intestinal resection, there occur transient ileus, gaseous and fluid distension of bowel, and later hypermotility. Sparkman (1952) and Cave (1953) reported cases of volvulus in the immediate postoperative period in which they thought that distension and hypermotility of the bowel were the exciting causes. It seems probable that this patient was subject to recurrent attacks of subacute primary volvulus and that the inguinal hernia was incidental. After the herniorrhaphy postoperative bowel distension and hypermotility were exciting causes in precipitating the final volvulus.

This case strengthens the view that postoperative distension can be an exciting factor precipitating volvulus, though a further predisposing cause is usually required. It emphasizes the necessity for observing carefully the progress of postoperative complications for any sudden deterioration that might call for urgent surgical treatment.

We are grateful to Mr. T. B. Field, who was in charge of this patient, for permission to publish this case.

Relation of Pregnancy Toxaemia to Trophoblastic Tumours

Brit. med. J., 1967, 3, 720

While the cause of pregnancy toxaemia remains obscure, the study of case histories of women with benign trophoblastic tumours (hydatidiform mole) serves to throw some light on this difficult subject.

The diagnosis of hydatidiform mole depends on four criteria: (1) a discrepancy between the expected and the actual size of the uterus, (2) the presence of pre-eclampsia before the 28th week of pregnancy, (3) a high urinary gonadotrophin excretion after the 16th week of pregnancy, and (4) the absence of foetal parts on radiology after the 16th week of pregnancy.

During 1958–64 250 cases of benign trophoblastic tumour were admitted to the General Hospital, Kuala Lumpur, and 66 (26.4%) of these had pre-eclampsia as defined by Dieckmann (1952), the disease being mild in 36 and severe in 30.

Size of the Uterus Related to Proportionate Incidence of Pre-eclampsia in Cases of Benign Trophoblastic Tumour

Size of Uterus	Total Cases	Pre-eclampsia	
		No.	%
Less than 12 weeks' pregnancy ..	8	0	0
12–15 „ „	17	1	6·0
16–19 „ „	75	10	13·3
20–23 „ „	78	22	28·2
24–27 „ „	55	22	40·0
28 or more „ „	17	11	64·7
	250	66	26·4

When the size of the uterus was related to the incidence of pre-eclampsia, it was noted that the greater the uterine size the more frequent was the associated finding of pre-eclampsia (see Table). But no correlation between the size of the uterus and the severity of toxaemia was noted.

COMMENT

That a higher proportionate incidence of pre-eclampsia was found in cases where the trophoblast was more active implies that abnormal trophoblastic activity rather than mechanical distension of the uterus is a precipitating cause of pre-eclampsia.

This opinion was further supported by the history of one of the patients who was admitted at 14 weeks' gestation with severe pre-eclampsia. She was Chinese, aged 24, gravida 2. Examination showed the uterus to be enlarged to the size of a 16-week gestation. A week after admission the uterus had enlarged to the size of a 20-week gestation, and the pre-eclampsia continued. Eight days after admission the signs of pre-eclampsia suddenly disappeared and no further uterine growth was noted. Intrauterine death was suspected, and as the uterus failed to expel the foetus spontaneously labour was induced with an oxytocin infusion on the 20th day after admission and a hydatidiform mole surrounded by fibrin and decidua was expelled.

Death from Paraquat after Subcutaneous Injection

Brit. med. J., 1967, 3, 721

Gramoxone is a commercial formulation of a herbicide containing the di-metho sulphate salt of paraquat (1,1′-dimethyl-4, 4′-dipyridilium).

Bullivant (1966) reported that up to July 1964 one case of paraquat poisoning had occurred in a child in Ireland. He described two additional cases in men in 1966. The first was that of a 28-year-old man who drank half a glass of 20% paraquat solution; a day later gastrointestinal symptoms appeared, followed by signs of hepatorenal damage. He died of severe respiratory failure. The second case was that of a man aged 23 who drank a mouthful of paraquat and vomited immediately. In this case also signs of mild hepatorenal damage appeared, and he too died of respiratory failure.

The purpose of this paper is to present an additional case of paraquat poisoning, this time by subcutaneous injection. Suicide in such an unusual way has not to our knowledge been described in medical literature.

CASE REPORT

The patient was a 30-year-old Yemeni-born farmer, divorced, who emigrated to Israel 21 years ago. He was known from the records of a mental hospital to suffer from paranoid schizophrenia.

On 2 August 1966, by means of a syringe that was used for immunizing chickens, he injected himself with approximately 1 ml. of a 20% solution of Gramoxone. He was admitted to hospital a few hours later after vomiting and passing loose bloody stools. He was found to be in good general condition. His pupils were equal and reacted to light. His pulse was 76 and blood pressure 130/80. No other abnormal physical findings were observed. Two days after admission a right facial paresis occurred, abdominal reflexes were reduced on the right side, and Oppenheim's sign was present on the left side. On the fifth day after admission these findings were no longer elicited. Laboratory findings were not abnormal except that urinary sediment contained some erythrocytes and leucocytes. Blood urea varied from 69 to 140 mg./100 ml. and urinary output from 1,000 to 2,000 ml. a day. An E.C.G. was within normal limits.

For two days after admission he felt well, but on the third day he complained of anorexia and chest pain, and his temperature rose to 39° C. He had no dyspnoea at this time. *X*-ray examination during this phase showed a slight infiltrative shadow of the right lung base. After five days he again improved, his pain disappeared, and his temperature returned to normal. In spite of this his radiological changes persisted. On the eighth day in hospital jaundice appeared.

He was tender in the right hypochondrium and the liver was felt 6 cm. below the costal margin. Total serum bilirubin values were raised to 4.6 mg./100 ml., of which direct bilirubin was 3 mg./100 ml., and the serum S.G.O.T. rose to 250 units. Serum ammonia was 375 µg./100 ml. and leucine aminopeptidase was 364 units. All these findings disappeared by the 11th day. The patient felt well for the next three days, but on the 14th day he developed dyspnoea and tachycardia, both of which increased in severity. *X*-ray examination of the chest showed bilateral areas of opacity and deviation of the mediastinum to the left. The patient became oxygen-dependent, and his condition worsened steadily until he died in severe respiratory distress on the 18th day.

Necropsy Findings.—The kidneys did not show any macroscopic or microscopical pathological changes; the liver did not show macroscopic changes, but histological examination revealed some swollen periportal hepatic cells. The main findings were found in the lungs; the upper lung segments were swollen and emphysematous, and there was evidence of intrapulmonary haemorrhages as well as subpleural petechial haemorrhages, the lower segments were contracted and showed bilateral atelectasis.

Microscopical Findings.—The most striking change was proliferation of epithelium of the terminal bronchioles. In many places this proliferation partly or completely occluded the lumen at the prealveolar ducts. The epithelial cells were themselves cuboidal with nuclei rich in chromatin (Reif and Herzig, 1967).

DISCUSSION

There are some findings common to our case and the two cases published by Bullivant (1966). All began with gastrointestinal disturbances, though in our case poisoning followed a subcutaneous injection, and evidence of hepatorenal damage followed the gastrointestinal disorders. Death was due to progressive pulmonary failure. Transient general neurological signs which were seen in our case were not mentioned in the two other cases, but in laboratory animals Clark *et al.* (1966) showed that initial neurological symptoms did occur. If the animal did not die during this phase the deaths were due to respiratory failure. Histologically, an identical pulmonary proliferative process was found, especially in rats and mice, and less in rabbits.

Daniel and Gage (1966), working with laboratory animals, showed that 96% of paraquat labelled with ^{14}C was excreted unchanged in the urine within three days of its subcutaneous administration.

We could not find paraquat in the patient's urine and sputum three days after admission. It seems, therefore, that this substance initiates proliferative changes, which continue though it itself is no longer present.

Such a proliferative process is not unique and has been said to follow the administration of carcinogenic compounds to laboratory animals (Ackerman and Regato, 1954). It is interesting to note that, after subcutaneous injection of carcinogenic hydrocarbons in high-pulmonary-tumour strains of mice, diffuse proliferative changes could, as early as two weeks, be detected, partly projecting into the lumen of alveoli. In the fifth week pulmonary tumours were diagnosed in some strains (Ackerman and Regato, 1954). We felt that this similarity should not be overlooked, and we suggest that further work should be done with paraquat to clarify its mode of action and to show whether or not it, too, is a carcinogen.

The estimated fatal dose would be 4 mg./kg., which would explain why only a mouthful of it could also be fatal despite the poor absorption of this type of compound.

It may be mentioned that the liver and kidneys did not show anything gross pathologically in spite of the presence of clinical hepatorenal infection.

We are grateful for the help given by Dr. A. Reif, head of the Department of Pathology at Asaf Harofe Government Hospital, and Dr. E. Herzig, assistant in that department. We wish to express our thanks to Dr. E. Vure, head of Paediatric Department "B" at the above hospital, for his helpful advice.

Insulin Allergy Treated by Low-dosage Hydrocortisone

Brit. med. J., 1967, **3**, 722

Allergy to insulin was a common problem in the early days of treating diabetes mellitus (Lawrence, 1925 ; Marble, 1959), but introduction of purified preparations has made this less likely. Allergic patients can usually be treated by desensitization or by changing the type of insulin (Marble, 1959).

Today many patients needing only small doses of insulin have been prescribed oral hypoglycaemic agents instead. However, these may be inadequate during infections or operations, or if the diabetes becomes worse, and so insulin may be given again. A secondary immune response is then apt to occur, causing local or general allergy and sometimes fatal anaphylaxis (Hanauer and Batson, 1961 ; Michel, 1963 ; Aiken, 1964). We encountered this problem in the following case and used a different method of overcoming allergy.

CASE REPORT

A 49-year-old housewife developed diabetes mellitus in 1960 and was given insulin zinc suspension. A few days later she developed painful red swellings at the injection sites. As her diabetes was mild insulin was stopped and tolbutamide substituted.

Five years later oral hypoglycaemic drugs failed. Isophane insulin controlled the blood-sugar level, but local allergic reactions again occurred. Soluble, globin zinc, and Actrapid insulins produced similar reactions whether injected subcutaneously or intramuscularly. After 13 days she developed a widespread urticarial rash, angioneurotic oedema, and dyspnoea. Antihistamines provided no relief, and so, as symptoms were severe and potentially dangerous, prednisone 10 mg. was given by mouth ; remission occurred within one hour.

After this her diabetes was controlled by soluble insulin (28 i.u. morning and 32 i.u. evening) and the allergy suppressed with prednisone by mouth 10 mg. q.d.s. However, on reducing the dose of prednisone below 20 mg. daily allergic symptoms recurred. As this dose was undesirable it was decided to inject a corticosteroid drug with the insulin. Prednisolone 2 mg. failed, but hydrocortisone 10 mg. prevented both local and systemic reactions. The blood-sugar level was controlled, there being no insulin resistance, and the patient improved. Within two weeks as little as 2 mg. of hydrocortisone mixed with each injection of soluble insulin was satisfactory. Less than this allowed skin reactions of increasing severity to recur and the patient used 2 mg. again of her own accord.

A limited supply of insulin recrystallized six times was used. This, while superior to soluble insulin alone, was not entirely free of allergic properties, occasionally producing weals with induration up to 1 in. (2.5 cm.) in diameter. The mixture of soluble insulin with hydrocortisone was therefore restarted. Hydrocortisone was omitted from trial injections at approximately fortnightly intervals until after about six months soluble insulin could be used alone without adverse effect.

COMMENT

The occurrence of allergy to several different types of insulin of bovine and porcine origin suggests that the reaction is to either insulin itself or to a constant impurity. The latter seems more likely because recrystallization of insulin lowers the incidence of allergy greatly (Jorpes, 1949, 1950).

Desensitization is a lengthy and sometimes difficult procedure, whereas suppression of symptoms with corticosteroids is simple. The use of hydrocortisone, which mixes well with soluble insulin, allows less corticosteroid to be employed, with reduced risk of adverse side-effects. In this case the dose was within the range of endogenous cortisol production 16.2 ± 5.7 mg./24 hours (Cope, 1965). Presumably slow desensitization then occurs under corticosteroid cover. The only disadvantage is the need to mix drugs for injection.

This method is suggested (1) as an alternative in simple cases of insulin allergy, (2) when speed is important, (3) in cases resistant to the more usual methods of treatment, and (4) when recrystallized insulin is not available.

We wish to thank Dr. C. F. Hawkins for constant encouragement and for permission to publish this case, and Dr. R. A. Ellis, of the Medical Division, Boots Pure Drug Company Limited, Nottingham, for supplying the insulin recrystallized six times.

"Railroading" in Retinal Vessels

Brit. med. J., 1967, **3**, 722–723

Among the many problems involved in the treatment of cardiac arrest is that of deciding during the period of emergency whether the brain has been damaged irreversibly and when resuscitation should be abandoned. Widely dilated pupils and stagnant cyanosis do not necessarily mean that the patient is dead. Obviously it is undesirable to continue resuscitation if the brain is dead. Treatment should be abandoned as soon as this is clearly indicated.

"Railroading" or "cattle-trucking" seen during ophthalmoscopic examination of the retina is a well-known physical sign of death in traditional medicine in Britain, though it is not well known in some other countries. This physical sign is not described in many of the standard textbooks, though a brief description is given by Smith and Simpson (1956). It may develop as late as several minutes after cessation of the heartbeat and it may be seen until the cornea clouds over.

What one observes is a fragmentation of the column of blood within the retinal vessels. The fragments or aggregates of red cells move in either direction along the vessel at random and may collide with each other. This has been fancifully likened to the sequence of events that occur when a trainload of unbraked goods wagons stops. Accompanying the movement of the red cells, the diameter of the vessels alters rapidly, sometimes narrowing, sometimes dilating. The vessel itself may appear to be moving rapidly in and out of focus of the ophthalmoscope. This may be erroneously attributed to an inability to use the ophthalmoscope during the stress conditions of treating cardiac arrest by those making the examination.

What is not known is the significance of this sign in situations of cardiac arrest. The association of the time of its appearance to the known time of survival of the brain after circulatory arrest suggests that it appears at or after death of the brain rather than with cessation of the circulation. This physical sign could provide a good guide to prognosis, as shown in this case report.

CASE REPORT

A girl aged 10, a severe asthmatic, was admitted to hospital having "collapsed" approximately 15 minutes earlier during an asthmatic attack at home.

On arrival she was intensely cyanosed, pulseless, and apnoeic. Cardiac massage and intermittent positive-pressure ventilation were started immediately and the cardiac arrest team was summoned. Ophthalmoscopic examination at this time showed widespread "railroading" in the retinal vessels. An E.C.G. showed ventricular fibrillation against a background of severe electrical interference. In view of the doubt on how long she had been in circulatory arrest it was decided to defibrillate the heart. This was done externally with a single shock and was immediately followed by good heart action. A later examination of the fundi showed normal vessel architecture, though there was widespread oedema of the fundi.

Despite dehydration therapy with mannitol, hypothermia, artificial ventilation, etc., she did not regain consciousness. An E.E.G. taken the next day with a portable electroencephalograph showed widespread abnormal activity with high-voltage spikes alternating with slow waves every one to two seconds. Regular spontaneous respiration did not return until eight days after admission.

Fourteen days after admission she developed pneumonia and died. At necropsy there was widespread diffuse infarction of the cerebral cortex, hypothalamus, right caudate nucleus, and pons.

COMMENT

This case illustrates that despite an easy restoration of the circulation the brain may still be irreparably damaged. Had this patient survived she would have been decerebrate. The outcome suggests that the appearances of the fundi at the time of arrest provided a good indication of the state of the brain.

In a series of 70 personally attended cardiac arrests occurring in 61 patients "railroading" has been seen on 14 occasions during the time of active resuscitation. Of these, despite persistence of resuscitatory effort for up to 30 minutes after making observations, the only occasion when the circulation was adequately restored was in the case described above. This is a marked contrast to the results of the overall series, in which 33 times out of 70 the circulation was initially restored adequately. For technical reasons fundal examinations were not always carried out.

If "railroading" has no significance nearly half of the 14 patients showing this sign might have been expected to have their circulation restarted. Instead only one did. On statistical grounds this may be regarded as significant (χ^2 9.32 ; $P<0.01$).

Nevertheless, in dealing with individual patients suffering from cardiac arrest such statistics relating to a single physical sign should not influence management unless the clinical significance of the physical sign is absolute—that is, the brain is always dead. The chances of full recovery after cardiac arrest are limited and the aim of instituting treatment is to improve these against the statistical certainty of death.

The preliminary observations presented here suggest that the presence of "railroading" is of grave prognostic significance, and it would be useful to know of any cases where this physical sign has been observed (and recorded at the time) and the patient has made a full neurological recovery.

Early ophthalmoscopic examination of the fundi in cardiac arrest is extremely easy because the pupils are usually widely dilated (if they are not, then this too is useful information). It can be carried out quickly with very little practice. Cardiac massage need not be stopped until a retinal vessel is seen, and then it need only be stopped momentarily. The one difficulty in making the very rapid examination of the fundi required in these circumstances is the presence of lens opacities. These may be readily seen with the ophthalmoscope held some 2 feet (60 cm.) away from the eye being examined. A green filter makes the retinal vessels appear black, and then they stand out even more clearly. A routine search for this physical sign when taken in conjunction with other features of such cases should establish its prognostic value.

I should like to express my thanks to D. J. S. Wigglesworth, Institute of Child Health, for the necropsy report.

Haemoperitoneum after Traumatic Avulsion of Uterine Fibroid

Brit. med. J., 1967, 3, 723–724

The causes of intra-abdominal haemorrhage can be divided into two main groups: those following traumatic injuries and those arising spontaneously.

In a review of 129 consecutive cases of haemoperitoneum, Ellis *et al.* (1958) noted that 68% were the result of gynaecological haemorrhage, 23% followed trauma, and the remainder resulted from a variety of causes. The gynaecological causes in their series were ruptured ectopic pregnancies and follicular cysts. Traumatic cases were usually the result of splenic, hepatic, or mesenteric injuries.

It is rare for haemoperitoneum to result from a gynaecological injury.

CASE REPORT

A woman aged 46 was admitted to Westminster Hospital on 14 January 1966 after a road accident in which she was knocked down by a car.

On admission she was concussed and shocked. Her blood pressure of 100/70 rapidly fell to unrecordable values. This was restored and maintained by blood transfusion. Her injuries included (*a*) a fractured pelvis, central dislocation of the right hip (Fig. 1), and a deep penetrating wound 3 in. (7.5 cm.) in diameter over the right greater trochanter; (*b*) a fractured neck of the left fibula with a lateral popliteal nerve palsy, and rupture of the lateral ligament of the knee; and (*c*) lacerations of the chin and buccal mucosa.

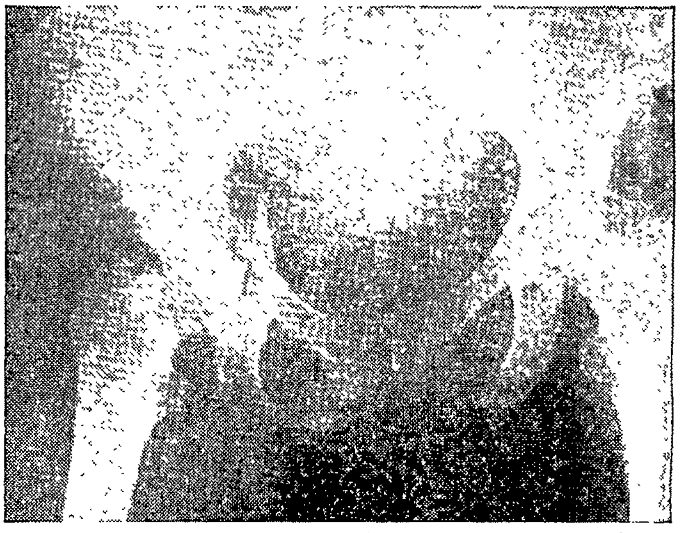

FIG. 1.—Radiograph of pelvis showing central dislocation of hip.

She complained of pain in her right shoulder—there was no external evidence of injury—and of lower abdominal tenderness. On abdominal examination there was tenderness and guarding over most of the lower abdomen which was maximal on the right near the pelvic brim. Rebound tenderness was elicited. Bowel sounds were present but diminished. The presence of free fluid was not detected clinically.

Chest *x*-ray examination showed a raised right diaphragm. A plain film of the abdomen did not demonstrate the presence of subdiaphragmatic gas. A catheter was passed to exclude any injury to the bladder or urethra and clear urine was obtained. It was thought that her symptoms and signs could be due to extraperitoneal haemorrhage alone, but as an intra-abdominal lesion could not be excluded laparotomy was undertaken.

Operation.—The findings were: (*a*) considerable intraperitoneal blood ; (*b*) an avulsed pedunculated fibroid measuring 8 by 7.5 by 5 cm. lying free in the peritoneal cavity (Fig. 2) ; (*c*) arterial bleeding from a raw area 2.5 cm. in diameter on the superior left surface of the uterus near the junction with the fallopian tube ; (*d*) a cyst of the right broad ligament 8 cm. in diameter ; and (*e*) extraperitoneal haemorrhage on the right side of the pelvis in relation to a central dislocation of the hip ; the peritoneum was intact. The raw bleeding area was oversewn and the broad-ligament cyst removed. Under the same anaesthetic the thigh wound was explored and found to be a deep penetrating wound with contamination. Debridement was performed and a Steinmann pin inserted into the right tibia.

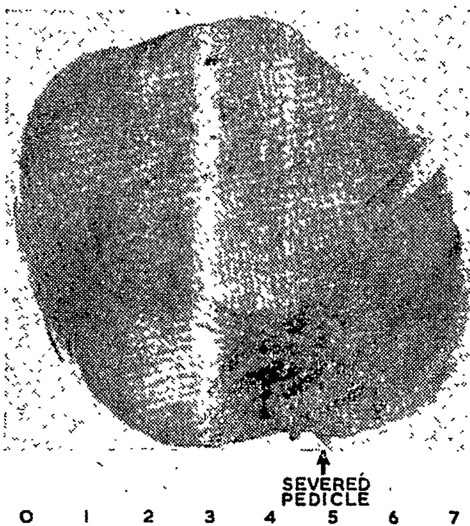

FIG. 2.—Avulsed fibroid with pedicle marked.

The patient was given a course of penicillin and streptomycin, and antitetanus and anti-gas-gangrene serum. The transfusion of 6 pints (3.4 litres) of blood was completed and continuous traction was begun.

Her recovery was uneventful until the fifth day after operation, when she became cyanosed, dyspnoeic, and disorientated. Signs of congestive cardiac failure were present. It was thought probable that this was due to fat embolism. She was treated with digitalis and diuretics and made a complete recovery.

Traction was maintained on her right leg for eight weeks and then gradual mobilization with increasing weight-bearing was begun. The movements of the right hip steadily improved and further *x*-ray examination of the pelvis showed consolidation of the fracture lines. The left lateral popliteal nerve palsy recovered and no abnormalities were detected on examination of the abdomen and of the cardiovascular system at follow-up.

COMMENT

The main feature of interest in this case was the presence of an avulsed fibroid and a fractured pelvis. We have been unable to find any previous report of this association.

It is known that fibroids may bleed spontaneously. Hasskarl (1949) collected 58 reports of cases where spontaneous bleeding occurred from dilated veins over the surface of fibromyomata. He excluded from his review those following torsion, though this does occur, as reported by Turel (1934).

We have traced only two cases where spontaneous separation of a fibroid caused intra-abdominal haemorrhage. The first (Shelley, 1931) was that of a woman aged 43 who complained of a sudden abdominal pain at rest. Laparotomy revealed haemorrhage from the pedicle of a separated fibroid lying free in the abdomen. The second (Cottalorda, 1935) was that of a patient who presented as a case of acute appendicitis. At operation the abdomen was filled with blood from the pedicle of a detached fibroid lying adherent to a gangrenous appendix in the pelvis.

We conclude that the most likely cause of the avulsion in our patient was a contrecoup type of injury, the uterus and fibroid moving at relatively different rates producing a sheering stress in the pedicle. There was no evidence to suggest torsion or direct injury.

We wish to thank Mr. David L. Evans for his permission to publish this case, Professor Ellis for his helpful advice, and the photographic department of Westminster Hospital.

Current Practice

MEDICINE TODAY

One or Two Fits

"Medicine Today" is the television series for doctors produced by the B.B.C. Advice in the preparation of the programme is given by the Association for the Study of Medical Education.

The programme on B.B.C. 2 on 12 September was on the subject of fits. Printed below is an article prepared with the help of expert contributors to complement the television programme, which will be repeated on B.B.C. 1 on 19 September at about 11.20 p.m.

In "Medicine Today" the crucial importance of a carefully taken detailed history in the diagnosis of true epilepsy was stressed, and this remains true despite the many impressive advances that have been made in investigative and diagnostic techniques. The distinction of fits from faints, the recognition of major, minor, and focal epilepsy, and the appreciation of possible provocative factors such as fever, television flicker, and intoxication with alcohol or lead are almost entirely dependent on traditional clinical methods. Analysis of the events prior to an attack of loss of consciousness may point to micturition or cough syncope; prodromal symptoms may establish the diagnosis of basilar artery migraine or temporal epilepsy; cryptic injuries, incontinence of urine, stiff muscles, and dull headaches on getting up in the morning may suggest unrecognized nocturnal major fits. Few of these obiter dicta will ring new to the experienced general practitioner. He is more likely to have witnessed the circumstances of an attack than is a remote consultant; he knows who may have been drinking excessively; as for possible precipitating factors he is only too familiar with the plethora of tortuous explanations and bizarre theories often advanced by puzzled patients or anxious relatives to account for a catastrophic and unheralded fit.

When to Investigate

However, all too often the facts are unequivocal. The patient has suffered one or two definite fits. There are no abnormal physical signs or evidence of systemic disease and the doctor is placed in the exacting position of having to decide when to investigate, when to refer, and how to treat. There is no simple answer. The possible variables influencing clinical judgement include age of patient, type of fit, number of attacks, interseizure period, recognizable provocative factors, occupational hazards, and local facilities for investigation; and the doctor must take all of these into account when deciding what advice to give to his patient.

To be helpful, advice to doctors facing this problem must be dogmatic. One or two febrile convulsions in an infant do not merit investigation nor do they require long-term anticonvulsants; the post-seizure electroencephalogram is usually normal and cannot distinguish the unfortunate 5% of infants who will develop recurrent attacks. In an otherwise healthy child a solitary fit usually means idiopathic epilepsy and detailed investigation is unrewarding, unjustifiable, and usually impracticable. At all ages anticonvulsant drugs should be given in effective doses or not at all; homoeopathic drug regimens usually reflect the prescriber's anxiety and indecision. In this particular context—a child with one fit—anticonvulsant drugs should be withheld until further attacks occur.

Focal fits are usually symptomatic of cerebral disease and prompt investigation may reveal a local and perhaps treatable lesion. It is pertinent to recall that in patients presenting with focal epilepsy the most sensitive investigation may remain normal for long periods before a cerebral tumour can be identified. Gliomas have been suspected but unproved for ten years or more. Investigations should include *x*-rays of skull and chest, an E.E.G., serological tests for syphilis, and examination of cerebrospinal fluid. Brain scanning is a painless procedure and can be done as an outpatient investigation. Detailed neuroradiological tests may be required: in skilful hands cerebral arteriography can be practised without great distress to the patient but air-encephalography, admittedly often a valuable procedure, may be followed by severe headache for several days.

Fits in Adults

The older the patient, the more probable is the fit to be symptomatic and the more taxing is the task of management and treatment. When employment or driving licence may be in jeopardy knowledge of previous fits may be withheld or repressed and remote attacks are easily overlooked. When physical signs are absent there is no clinical guide other than the laws of chance to distinguish the patient who may have only one or two attacks of idiopathic epilepsy during a lifetime from the patient who may be harbouring a cerebral tumour. If a healthy adult appears to have had only one recent fit and *x*-rays of skull and chest and an E.E.G. are normal, many neurologists would prefer to leave the patient observed, undiagnosed and untreated. However, the patient's occupation—lorry driver, pilot, or steeplejack—or a second fit shortly after the first will enforce drug treatment and more stringent investigations. When the interval between the two fits is long, say a year or so, and the patient still appears to enjoy good health there is no uniformity of opinion concerning long-term drug treatment. An anxious professional man would probably require drugs while an elderly stoic benevolently contemplating a long and untreated remission might prefer to "wait and see." Assuming that the fits are not focal and that an adult patient who has had only one or two fits is otherwise well, detailed investigation is unlikely to be therapeutically rewarding. It is true that the possible symptomatic causes of epilepsy are legion, from uncommon cerebral tumours to intriguing but improbable biochemical disturbances such as hypocalcaemia, but it is manifestly unrealistic and unreasonable to investigate every patient intensively. Even the most erudite and obsessional of neurologists defers consideration of rare polyeponymous (and usually untreatable) systemic degenerations of the central nervous system until more than a couple of fits have occurred. *X*-rays of skull and chest should be done; if available an electroencephalograph might serve towards excluding a focal cerebral lesion. Most decisions in clinical medicine are still determined by common sense and probability and it is important to recall that idiopathic epilepsy is a much commoner cause of fits than is cerebral tumour, even when the first fit occurs after the age of 25 years.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Oral Contraceptives and Carbohydrate Metabolism

Q.—*Do oral contraceptives have any effect on carbohydrate metabolism and on the insulin requirements of diabetics? If so, what is the effect and what is its mechanism?*

A.—Wynn and Doar[1] reported minor abnormalities of glucose tolerance in approximately 20% of people taking a variety of oral contraceptive preparations. They suggested that the effect was similar to that found in corticosteroid diabetes and during pregnancy. The insulin requirements of a diabetic might therefore be increased on occasion, but the effect is not likely to be very great.

Scleroderma

Q.—*What is known about the aetiology and pathology of scleroderma, and is there any treatment?*

A.—The term scleroderma is used for two quite distinct clinical entities: morphoea, characterized by the transient appearance of sclerodermatous plaques without any evidence of systemic involvement, and systemic sclerosis, one of the major generalized collagen-vascular diseases with sclerodactyly and widespread sclerodermatous changes secondary to peripheral ischaemia.[1]

With the exception of linear morphoea, which may affect by direct extension the underlying tissues of the skull and limbs, morphoea is a benign and self-healing disorder. There is recent experimental and clinical evidence that the chelating agent penicillamine is of benefit in this condition by interfering with the excessive formation of dermal collagen.[2 3] An initial dose of two capsules (300 mg.) t.d.s. of penicillamine for one month with gradual reduction of the dose to one capsule (150 mg.) on alternate days is effective in most patients.

Treatment of systemic sclerosis should always be preceded by a full investigation of the renal, respiratory, and alimentary systems. Treatment with oral corticosteroids is disappointing unless they are given in high dosage during periods of rapid progression of the disease. Apart from clinical assessment, frequent repetition of pulmonary function tests is a useful guide to progress. The often grossly impaired peripheral blood flow, with digital ulcers, sclerodactyly, and widespread sclerodermatous changes, can be improved by infusions with low molecular dextran, two to six bottles being given at the rate of one bottle in 12 hours. This treatment has to be repeated every four to six weeks during the winter and every two to four months during the summer.[4]

Shampoos in Seborrhoea

Q.—*Is long-continued use of a shampoo of either cetrimide or a coal-tar preparation with hexachlorophane contraindicated in cases of seborrhoea?*

A.—The prolonged application of any chemical to the skin involves a risk of inducing allergic sensitization. Tar, hexachlorophane, and cetrimide are all potential sensitizers but relatively feeble ones. The use of these substances in scalp preparations can be regarded as safe. Used in this way they very rarely indeed induce allergic dermatitis.

Diphtheria Immunization of Nurses

Q.—*Does a prospective nurse require a full course of immunization against diphtheria if the Schick test is positive? If it is negative, what is the best method and preparation to use?*

A.—Schick-positive nurses should be given a full immunizing course of diphtheria toxoid consisting of either two injections of P.T.A.P., 0.2 ml. and 0.5 ml. respectively, or three 0.5-ml. doses of T.A.F. with an interval of not less than four weeks between injections. P.T.A.P. is a more potent antigen than T.A.F., and is therefore preferred despite its tendency to cause undesirable local reactions.

A negative Schick reaction is generally regarded as indicative of immunity to diphtheria, but this immunity is not always absolute and may be occasionally overcome by heavy infection of the gravis type. Prospective Schick-negative nurses should therefore be given a single booster injection of a diphtheria toxoid, preferably 0.2 ml. P.T.A.P.

Nurses with pseudo-positive Schick reaction are prone to react violently to diphtheria toxoids, but since they are immune to diphtheria they do not require further immunization.

Reaction of Triple Antigen

Q.—*Is it better to begin a course of triple antigen at the age of 3 months or of 6 months, when the risk of side-effects is less?*

A.—There is little evidence to support the view that side-effects to triple antigen are reduced by starting a course of immunization at 6 months instead of 3 months.

In a recent report on reactions to combined vaccines contained killed *B. pertussis*[1] it was stated that 23 of the 24 infants who had severe reactions to the first dose of *quadruple* vaccine (which included trial batches of vaccine) were under 6 months of age, though there were almost equal numbers of participants below or over 6 months. On studying the report further, it can be deduced that three of the six children who had severe reactions to second injections were over the age of 25 weeks, but the age distribution at the time of second injections is not known.

With regard to reactions following *triple* antigen, only two groups of sixty were immunized. The purpose of the study was to compare the incidence and severity of reactions produced by two manufacturers' vaccines. Six children aged 18 to 21 weeks had severe reactions, but it is possible that the study was confined to infants of this age.

These studies do not provide adequate evidence to justify changes in existing immunization schedules. Such changes should not be considered on the grounds of reactions until results are available on direct comparative trials in 3- and 6-months-old infants.

Stability of Hyoscine

Q.—*Do tablets of hyoscine keep their properties over long periods, and after, say, seven years could their strength and safety be relied on?*

A.—Hyoscine may be present in proprietary tablets either as the base or as a salt, usually the hydrobromide. In either case the substance is reasonably stable. Solutions of the salts can, for example, be sterilized by autoclaving.

If the tablets have been stored under the official conditions—protected from air and light in a cool place—they should retain their strength for several years, possibly as long as seven. Most pharmacists, however, regard about five years as the maximum shelf-life of any medicine.

There are unlikely to be any toxic products in tablets stored for seven years, but there may be some physical deterioration of the tablets.

Warmed Air and Asthma

Q.—*Is central heating by way of warmed air circulated through ducts likely to aggravate asthma and upper respiratory tract allergic conditions? Some asthmatics complain of this form of heating and think that dust and allergens may be circulated with the air.*

A.—I know of no evidence that central heating by warmed air circulated through ducts is likely to aggravate asthma or upper respiratory tract allergic conditions. It has been suggested that some asthmatics are better when the absolute level of moisture in the air is high, and it is possible that excessive drying of the air might lead to deterioration.

Treatment of Cataract

Q.—*Have injections of dilute hydrochloric acid any role in the treatment of cataract?*

A.—I know of no medical treatment which has been proved to have any value in the treatment of senile cataract, and I have no knowledge of the use of hydrochloric acid for this purpose.

Book Reviews

Autistic Children

Early Childhood Autism. Clinical, Educational and Social Aspects. Edited by J. K. Wing. (Pp. 333+xiii. 45s.) Oxford: Pergamon. 1967.

The Nature of Childhood Autism. By Gerald O'Gorman, M.R.C.P., D.P.M. (Pp. 134+vii. 30s.) London: Butterworth. 1967.

Most mentally retarded children are fairly uniformly backward in all their accomplishments. Those who are of trainable or imbecile level of intelligence are often cheerful, pleasant, and outgoing. The use of the term "idiot savant" was an early recognition that some patients are not uniformly retarded but are relatively advanced in some aspects of their performance while severely handicapped in others. It is probable that most patients who have previously been described as "idiot savant" would now be classed as autistic. With the passage of time more and more groups of handicapped children who present a special variety of problems have been recognized and attempts have been made to make special provision for them. This has happened in the case of autistic children, and there is now a voluntary body concerned with their interests. There is, however, a considerable lack of agreement about the precise nature of infantile autism or its definition; even the terminology is not agreed. Some authorities use "infantile schizophrenia" as covering much the same ground as "infantile autism," and still others prefer to use the term "infantile psychosis."

In view of the interest attaching to this subject at the present time it is fortunate that two volumes which should contribute to our knowledge of the problem have now appeared. The work edited by Dr. J. K. Wing is a composite effort by 11 contributors. Much of the material is derived from the Maudsley Hospital children's department, in particular Dr. M. L. Rutter's contribution. It is now well recognized that adequate provision for handicapped children requires a team approach, and this principle has been followed in Dr. Wing's book, which includes chapters by psychologists, a teacher, and a mother of an autistic child.

The chapter by V. Lotter deals with the survey carried out in the county of Middlesex on children aged 8, 9, and 10. On the basis of an extensive inquiry 61 children were selected as possibly autistic. Of these 35 were ultimately selected as being in fact autistic, giving a prevalence of 4.5 autistic children per 10,000 of the population. This is equivalent to 3,049 autistic children in England and Wales, of whom 1,287 would have an intelligence quotient of 55 or above on testing. On this estimate there are about as many autistic children as deaf children of school age, and about twice as many autistic as blind children. It should be emphasized, however, that in this survey and in other work on the subject no sharp cut-off point is found, and the 26 children who were excluded as not satisfying the criteria did in fact show some features of autism. Dr. Wing dislikes the use of the term infantile schizophrenia for this group of patients, preferring infantile autism or Kanner's syndrome. He says that none of the positive features of schizophrenia, such as specific kinds of delusions or hallucinations, occur in autistic children, and he also states that none of the well-documented series has demonstrated an increased risk of schizophrenia in the relatives.

Rutter points out that the prognosis for autistic children correlates fairly well with assessment of intelligence, as carried out by experienced psychologists, who usually have the opportunity of seeing the child on several occasions during the course of the stay in hospital. He emphasized that psychotic children are notoriously difficult to test and much patience and ingenuity are required. In spite of the bad prognosis with many such children, a number of successes have been recorded and it seems likely that with better educational facilities there would be more. O. I. Lovaas and other contributors to Dr. Wing's volume stress the need for a structured educational environment in teaching. A purely permissive attitude does not seem to be helpful with these children, who showed marked psychological rigidity or resistance to change. Dr. P. H. Connell's chapter mentions the many deficiencies in services. He points out that adequate numbers of comprehensive assessment units are not available and that there are very few day or residential schools. Despite this, however, he hopes that the needs of the autistic child will not be considered in isolation, but in relation to wider issues and other handicaps appearing during childhood.

The other new volume on the subject is by Dr. Gerald O'Gorman, whose work at Smith Hospital, Henley-on-Thames, in connexion with infantile psychosis is well known. He considers that the term childhood schizophrenia is appropriate for this group and points to examples of families with more than one case and with parents affected by schizophrenia. However, as he suggests, it is probable that arguments about terminology are not very appropriate, and most readers of these two volumes will be interested in the powerful plea made by all the writers for more research, more study, more objective appraisal, and more services for this group of very disturbed children.

B. KIRMAN.

Rheumatic Diseases

Modern Trends in Rheumatology. Vol. 1. Edited by Alan G. S. Hill, M.C., F.R.C.P.(Ed.), M.R.C.P. (Pp. 394+xii; illustrated. 95s.) London: Butterworth. 1966.

This is a well-illustrated and well-produced book. Most of the contributors are from Great Britain, but authorities from the United States are also represented. Daniel McCarty writes on calcium pyrophosphate crystal deposition disease, John H. Talbott on gout, Peter Kulka on vascular derangement in rheumatoid arthritis, Alan Cohen and Chang Kim on acute suppurative arthritis, and W. B. Reed on psoriatic arthritis. W. Hijmans, of Leiden, writes an interesting chapter on the L.E. cell phenomenon and the antinuclear factors. In an active growing subject such books as these are essential, and there is abundant room for this publication, even though *Progress in Clinical Rheumatology*, edited by A. St. J. Dixon, appeared less than two years ago, for the books do not cover the same ground, and have a different approach.

The present volume is well set out, and many of the chapters end in a summary or abbreviation of their contents. The syndrome "polymyalgia rheumatica" is shortly and adeptly discussed by F. M. Andrews, of Reading, who recommends a search for vascular tenderness, and a biopsy if it is found, so that the relationship of the syndrome to giant-cell arteritis can be finally elucidated. Gerald Rodnan contributes a useful chapter on diffuse scleroderma, and Carl M. Pearson on polymyositis and dermatomyositis. The chapter by Daniel J. McCarty on "pseudo-gout" due to deposition of crystalline material of different kinds is clear and informative. The opening chapter on epidemiology of the rheumatic diseases is ably done, as would be expected from such an acknowledged expert on the subject as J. S. Lawrence. The editor modestly does not contribute more than a foreword, but the whole work bears the stamp of his efficient selection and supervision. This is an essential book for anyone interested and working on this important and ever-growing subject.

F. DUDLEY HART.

Gynaecological Cancer

New Concepts in Gynecological Oncology. Edited by George C. Lewis, jun., M.D., W. Budd Wentz, M.D., and Ronald M. Jaffe, M.D. (Pp. 438+xxviii; illustrated. £8.) Oxford: Blackwell. 1967.

This book consists of 49 lectures and contributions to a symposium, with an introduction by S. L. Israel and R. J. Bolognese. In his preface the senior editor declares that its main purpose is "to provide a broad review of the present status of gynaecologic cancer." It does exactly this. The reader is presented with modern rather than new concepts, and these by eminent contributors, all except a few of whom work in the U.S.A.

There are two sections on squamous carcinoma of the cervix, two on adenocarcinoma of the endometrium, one each on ovarian tumours, carcinoma of the vulva, and trophoblastic tumours, with a final special lecture by Langdon Parsons on treatment centres and education of the physician. In addition to clear accounts of pathology, premalignant states, diagnosis, and treatment, attention is paid to the epidemiology of certain cancers, to fields in which research is active, and to the physician's responsibility for cancer control. Often one subject is dealt with by more than one authority, and this naturally reveals a few delightful differences of opinion and experience. Thus, a pathologist says that most chronic skin lesions of the vulva deserve conservative management, whereas a surgeon holds that all "leukoplakic" skin requires radical excision. Nevertheless, the work as a whole presents a concise and comprehensive picture with full details of surgical, radiotherapeutic, and chemotherapeutic techniques. The statements on results are balanced and fair.

Those who are at present concerned to encourage population screening with a view to detecting cancer at an early stage should study especially the relevant chapter, which includes the ten-point programme of the American Cancer Society. This makes it abundantly clear that all screening, including cervical cytodiagnosis, requires to be of the highest standard if it is to be valuable. This applies to both the clinical and laboratory aspects.

This book is expensive but it is worth the money, for it is beautifully produced and offers what must be one of the best available statements of present-day knowledge of the most common types of female pelvic cancer.

T. N. A. JEFFCOATE.

Statistics in Malaria Eradication

Statistical Methods in Malaria Eradication. By Satya Swaroop. (Pp. 164. £1 3s. 6d.) Geneva: W.H.O. 1966.

This monograph on statistical methodology is to help those engaged in malaria eradication. In 1956 Dr. Swaroop (then chief of the statistical studies section, W.H.O.) produced a cyclostyled document entitled "Statistical Notes for Malaria Workers." This was so well received that it was revised as "Statistical Methodology in Malaria Work." This was in two parts, yet a further version became necessary—this time called "Statistical Consideration and Methodology in Malaria Eradication."

The present volume is a revision started by Dr. Swaroop, interrupted by his untimely death in 1962, and completed by Dr. Gilroy. The chapters are devoted to: malariometric rates and population indices; collection and classification of statistical data; record cards: their design and uses; diagrams and their uses; the use of sampling in eradication programmes; sample size for field investigations; frequency distributions; the analysis of qualitative data; the analysis of ungrouped quantitative data; the analysis of grouped data; insecticide susceptibility tests; and the quantitative epidemiology of malaria. Annexes give a table of random numbers and tables of various statistical values.

The history and development of this monograph are a testimony to its usefulness and quality. In this increasingly noisy Tower of Babel in the communication of science it is brief, and by dint of careful selection in both inclusion and exclusion complete in itself.

WILLIAM KERSHAW.

Eye Disease

Modern Trends in Ophthalmology—4. Edited by Arnold Sorsby, C.B.E., M.D., F.R.C.S. (Pp. 272+ix; illustrated. £3 10s.) London: Butterworth. 1967.

This is a smaller book than its predecessors, and though published in London and compiled by Arnold Sorsby, emeritus research professor in ophthalmology at the Royal College of Surgeons, is an international product, eight of the authors being American, four British, one German, and one Swiss. It aims not to cover the whole field of ophthalmology or even all the section under discussion but rather to highlight the growing points in which there have been recent developments. The technique and more accurate diagnosis which can result from fluorescein retinal photography and the potential value of ultrasonography are discussed. Recent work on some of the rarer types of glaucoma and on infections, nutritional, and vascular diseases involving the retina and choroid are described, and the final chapters deal with modern methods of treatment of corneal opacities and cataract surgery and contain a concise account of the present methods of replacing detached retina employed at one noted American clinic.

There must be many thousands of ophthalmic surgeons the world over who, under the pressure of heavy work, are unable to keep pace with the exceptionally voluminous literature which pours forth on the eye and its relations with systemic disease, for there is scarcely a part of the body with which ocular disease may not be in some way connected. To these this book, which can be read in a week-end, provides the opportunity of a brief but authoritative home refresher course.

HAROLD RIDLEY.

Symposium on Steroids

Research on Steroids. Transactions of 2nd Meeting of International Study Group for Steroid Hormones. Vol. 2. Edited by Cataldo Cassano. (Pp. 553+xv; illustrated. No price given.) Rome: Il Pensiero Scientifico. 1966.

In recent years an ever-increasing proportion of published work has appeared in book form as the proceedings of an international conference of some highly specialized group of scientists. This has the advantage that a large number of related papers are collected together in the confines of one volume. It also means that many interested specialists who were unable to attend the conference can share in the fruits of the meeting. There are, however, a number of disadvantages and dangers. Work published in this way may not be so generally available as if it had appeared in regular journals. More serious, perhaps, is the criticism that such work is not subjected to the normal editorial process, so that experimental details may be inadequate.

Lack of experimental detail and failure to give adequate references are to be found in some of the contributions to this report of an International Study Group which met in Rome in December 1965. The book is divided into three parts. The first part consists of four lectures and 11 communications on the general subject of "Oestrogens in Pregnancy." The second part contains four lectures and 16 communications on "Methodology in Steroid Estimation." The last part is a round-table conference on "Steroidal Antifertility Agents."

A notable feature of the first section is an excellent review by E. Diczfalusy and G. Benagiano on "Oestriol Metabolism in Mid-pregnancy." This lecture emphasizes the important role of the foetus in the placental synthesis and conjugation of oestriol. Practical applications of these concepts are dealt with by A. Klopper, who describes the value of estimations of urinary oestriol in the assessment of placental function and foetal viability. A number of short communications to this section are also concerned with this subject.

The second section, on methodology, begins with a lecture by E. C. Horning and W. L. Gardiner on the "Estimation of Human Steroids by Gas Liquid Chromatography." Many of the communications in this section describe specific methods for the determination of oestrogens, androgens, or corticosteroids in body fluids. There is also an excellent lecture by R. De Hertogh on "Isotopic Methods in the Study of Steroid Hormone Metabolism in vivo." This reviews the calculation of secretion rates using both urinary and blood methods and also the complications which ensue when there is interconversion of hormones within the body.

The final and largest section of the book contains 30 contributions on steroidal antifertility agents. Most of these papers are followed by some discussion. A number of the earlier contributions, especially those by L. Martini, J. Haller, and E. Diczfalusy, deal with the mechanism of action of antiovulatory steroids. The greatest number of papers report the effects of these steroids on the female genital tract and the menstrual cycle. The remaining papers are concerned with effects on other organs—for example, the adrenal cortex (G. Sala), thyroid (I. De Salcedo), liver (D. Bayot) and on the coagulation of blood (H. L. Krüskemper). The volume is completed by an excellent list of 114 antifertility preparations with structural formulae of their component steroids.

In summary this book is a valuable source of information for anyone concerned with either the biochemistry of steroids or the endocrinology of reproduction.

R. V. BROOKS.

Nurses' Progress

The Lamp and the Book. The Story of the R.C.N. 1916-1966. By Gerald Bowman. (Pp. 206; illustrated. 21s.) London: Queen Anne Press. 1967.

In 1966 the Royal College of Nursing celebrated its jubilee. To commemorate this its history has now been published, the College retaining the copyright. The writing of it was entrusted not to a nurse but to an author of distinction, who received help and assistance from members and the staff of the College.

The College is concerned with promoting the science and art of nursing, looks after the interests of nurses, holds educational courses, and grants certificates. Since 1916 more than 120,000 nurses have been admitted to its membership.

Florence Nightingale made nursing a profession; and Dame Alicia Lloyd Still, successively matron of Brompton Hospital, the Middlesex Hospital, and St. Thomas's Hospital, a woman of outstanding administrative ability, sympathy, and knowledge, continued her noble work. Dame Alicia had also a large share in the founding of the College. Other founders recorded here were: Miss Cox-Davies, matron of the Royal Free Hospital, who persuaded Lady Cowdray to give the College its present building in Henrietta Place, Cavendish Square, at the cost of some half-million pounds; Dame Sarah Swift, matron-in-chief of the British Red Cross; Sir Arthur Stanley, treasurer of St. Thomas's Hospital; Sir Cooper Perry, consulting physician to Guy's Hospital; and Sir Comyns Berkeley, consulting obstetrician to the Middlesex Hospital.

Mr. Bowman also gives an account of the general progress of nursing in the nineteenth and present centuries, including State registration of nurses; the General Nursing Council; nursing legislation; and the Athlone, Horder, and Rushcliffe Committees, sponsored by the Ministry of Health. Possibly, through exigencies of space, his account of the Government's preparations for nursing in wartime is a little incomplete; and, while paying due tribute to Mrs. Bedford Fenwick's zeal and work for nurses, he dwells at too great length on the defects of her qualities. These are minor criticisms of an excellent book, which deserves many readers.

ARTHUR S. MACNALTY.

Books Received

Review is not precluded by notice here of books recently received.

Emergencies in Medical Practice. 8th edition. Edited by C. Allan Birch, M.D., F.R.C.P. (Pp. 852+xvi; illustrated. 60s.) Edinburgh and London: E. & S. Livingstone. 1967.

Nursing Emergencies. By P. S. London, M.B.E., F.R.C.S. Foreword by Mary Powell, S.R.N., M.C.S.P. (Pp. 262+x; illustrated. 30s.) Oxford: Blackwell. 1967.

Transactions of the International Chest and Heart Conference. Eastbourne, 1967. (Pp. 219 + Supplement 202 pp. £2 2s.) London: Chest and Heart Association. 1967.

Studies of Rheumatoid Disease. Proceedings of 3rd Canadian Conference on Research in the Rheumatic Diseases. Toronto, 1965. (Pp. 322+xi; illustrated. £7.) Toronto: University Press. London: Oxford University Press. 1967.

Radiobiological Factors in Manned Space Flight. Edited by Wright H. Langham. (Pp. 274+xvii. $7.50.) Washington: National Academy of Sciences–National Research Council. 1967.

Symposium on Shock. Report of the Proceedings held in Dublin, 1966. Edited by Professor Patrick FitzGerald, M.Sc., M.D., M.Ch., F.R.C.S.I. (Pp. 71. No price given.) Uppsala, Sweden: Pharmacia International. 1967.

Replacement of Renal Function. Proceedings of the European Dialysis and Transplant Association. 1966. Vol. 3. Edited by David N. S. Kerr. (Pp. 400+xxiii; illustrated. £7 10s. 9d.) Amsterdam: Excerpta Medica. 1967.

Danni da Sport Agonistico nell'Età Evolutiva. By Professor Enrico Tatafiore. (Pp. 93. No price given.) Naples: Ospedale "Santobono." 1967.

Reading and Health. Papers given at the Hospital Libraries and Handicapped Readers Group Conference. (Pp. 51. 12s. 6d.) London: The Hospital Libraries and Handicapped Readers Group, Library Association. 1967.

A Surgeon's Guide to Cardiac Diagnosis. Part 2. The Clinical Picture. By Donald N. Ross, B.Sc., M.B., Ch.B., F.R.C.S. (Pp. 88+viii; illustrated. $6.00.) Berlin, Heidelberg, and New York: Springer. 1967.

Practical Cytology. By R. G. W. Taylor. (Pp. 148+xi; illustrated. 39s. 6d.) London: Academic Press. 1967.

Ultrastructure of the Kidney. Ultrastructure in Biological Systems. Vol. 2. Edited by Albert J. Dalton and Françoise Haguenau. (Pp. 240 +x; illustrated. £5 12s.) London and New York: Academic Press. 1967.

Mathematical Challenges to the Neo-Darwinian Interpretation of Evolution. Wistar Institute Symposium Monograph No. 5. Edited by Paul S. Moorhead and Martin M. Kaplan. (Pp. 140 +xi. $5.00.) Philadelphia: Wistar Institute of Anatomy and Biology. 1967.

Obstetrics and Gynaecology in the Tropics and Developing Countries. By J. B. Lawson, M.A., M.B., B.Chir., F.R.C.O.G., and D. B. Stewart, M.B.E., B.Sc., M.D., F.R.C.S.(C.), F.R.C.O.G. (Pp. 630; illustrated. £8.) London: Edward Arnold. 1967.

Lipid Metabolism in Tissue Culture Cells. Symposium held at the Wistar Institute of Anatomy and Biology. Edited by George H. Rothblat and David Kritchevsky. (Pp. 164+vii; illustrated. $5.00.) Philadelphia: Wistar Institute. 1967.

Through Youth to Age. Proceedings of the Fourth International Congress of the World Federation of Occupational Therapists, London. Edited by R. L. Kleinman. (Pp. 431; illustrated. $15.60.) Amsterdam: Excerpta Medica. 1967.

The Connective Tissue. International Academy of Pathology Monograph. By 30 authors. Edited by Bernard M. Wagner, M.D., and David E. Smith, M.D. (Pp. 408+xi; illustrated. £7.) Edinburgh and London: E. & S. Livingstone. 1967.

Scientiae Pharmaceuticae. Vol. 1—Symposium: Cardioglucosides. Vol. 2—Symposium: Identification of Drugs. Edited by Dr. Oldrich Hanc and Dr. Josef Hubik. (Pp. 496+xiii. Pp. 639 +ix; illustrated. £10 10s. per set of two volumes.) London: Butterworth. 1967.

Pathology. 3rd edition. By Stanley L. Robbins, M.D. (Pp. 1434+x+xxvi; illustrated. £7 3s. 6d. Two-volume set £8 15s. 6d.) London: W. B. Saunders. 1967.

Manual of Preoperative and Postoperative Care. By the Committee on Pre- and Post-operative Care, American College of Surgeons. Editorial Subcommittee: Henry T. Randall, M.D., James D. Hardy, M.D., and Francis D. Moore, M.D. (Pp. 506+xiv; illustrated. £2 19s. 6d.) London: W. B. Saunders. 1967.

Novak's Gynecologic and Obstetric Pathology. With Clinical and Endocrine Relations. 6th edition. By Edmund R. Novak, A.B., M.D., and J. Donald Woodruff, B.S., M.D. (Pp. 696 +xvi; illustrated. £7.) London: W. B. Saunders. 1967.

Radiation Therapy. 2nd edition. By Walter T. Murphy, M.D. (Pp. 1030+xiii; illustrated. £15 15s.) London: W. B. Saunders. 1967.

Collection of Unwanted Drugs from Private Homes

W. A. NICHOLSON,* M.D.

Brit. med. J., 1967, 3, 730–731

It is not uncommon to find that the unused portions of medicines and tablets prescribed are left on shelves in private houses long after the need for them has ended. It was suspected that this stock might be quite large, and in March 1967 a week's collection was arranged in the Hartlepools, designed to fit in with the normal period of spring cleaning. The then West Hartlepool† Health Department provided posters to be displayed in their departments, the local pharmacies, doctors' waiting-rooms, and the local hospitals. The pharmacists agreed to act as collecting-points from which the Health Department brought the results to the General Hospital, West Hartlepool.† for counting and identification. The collection went on from 13 to 18 March. Considerable local publicity was given by the press and television services. The numbers collected are shown in Table I.

TABLE I

Tablets and capsules ..	43,554	Ear-drops (bottles)	13
Ampoules	194	Nasal drops (bottles)	17
Bottles of medicine ..	83	Lozenges	131
Liniments	16	Powders and cachets	123
Ointments and lotions ..	56	Pessaries and suppositories ..	178
Eye-drops and ointments ..	17	Miscellaneous	46

The number of separate items was 1,395.

TABLE II.—*Tablets, Capsules, and Ampoules Identified*

	Tablets and Capsules	Ampoules
Antacids	755	
Gastric sedatives and antispasmodics	2.679	
Laxatives	1,331	
Anticoagulants	39	1
Cardiac and cardiovascular reactants	1,674	2
Vasoconstrictors	871	
Antimigraine agents	146	
Analgesics	4,571	
Anti-inflammatory agents	392	1
Hypnotics	2,179	
Anticonvulsants	303	
Sedatives and tranquillizers	4,719	11
Thymoleptics	423

Cough suppressants and bronchial spasm relaxants	2,197	2
Antiobesity agents	541	
Miscellaneous	631	4
Total	36,242	194

62 packets of Inpasade were also handed in.

Tablets were identified by determining their diameter by passing them through slots ranging from 5/32 to 22/32 in. (4 to 17.5 mm.) in a specially made steel disc. The references used in identification were: (1) *The Chemist and Druggist* tablet and capsule identification guide; (2) *Medindex*; (3) the punch-card system devised by Mr. C. M. McArdle, chief pharmacist at Birmingham General Hospital; (4) information provided in the literature of some drug firms.

The general findings are shown in Table II and details of some of these are given in Table III.

Penicillamine	200

It was not possible to state accurately the number of households involved, but it is thought to be no more than 500. There are about 30,000 households in the area, with a population of 100,000. If the same pattern obtained in the remaining households we might have collected over 2,500,000 tablets and capsules. The identified finds were priced roughly on the basis of N.H.S. costs per 100, and a cost of £220 was obtained. Given a total clear-out for the area, this would represent about £13,200. On a United Kingdom basis the numbers and cost would be staggering.

Some of the "hoards" were probably "left-overs" from houses where there had been a death. The biggest hoard was 1,200 tablets from a house where an elderly woman had died just before the collection started. It included Guy's pills 179, Blaud's pills 85, calomel 1 gr. (65 mg.) 78, calomel ½ gr. (32 mg.) 85, Bellergal 234, various analgesics, laxatives, and a tin of rat poison; it seemed to represent a lifetime of discarded treatment. The hoards of pethidine were no doubt left-overs from deaths from cancer. But doctors cannot be acquitted of some overprescribing. The pethidine hoards were 10 in number, and two contained over 100. There were other large single hoards—Largactil 576, Seconal 209, Librium 170, Monidine 302, Valium 159, Chloromycetin 300, Fersamal 261, Lasix 190. Against the accusation of overprescribing, it must be remembered that a patient may be given a course of treatment and the treatment may be changed, or the patient comes into hospital or dies or may decide not to continue the treatment. The remnants of the prescription usually then go on to a shelf in case they may be needed again. In time the original use is forgotten or the drugs may cease to be effective. They may be offered to relatives or friends on the basis of "these did me good, they may help you." I have seen a case of glaucoma precipitated by the misuse of an atropine-containing ointment, and combinations of tablets can be very dangerous. There is the risk of distraught persons taking any tablets available in an act of self-poisoning. In 1965 a man was admitted here with thalidomide poisoning. If the patient had been a pregnant woman the results would have been disastrous. Also there is the risk to children, for drugs in homes are seldom properly guarded and so many tablets look like sweets.

---

* Consultant Physician, the General Hospital, Hartlepool.

† The County Borough of West Hartlepool and the Borough of Hartlepool amalgamated on 1 April 1967 to form the County Borough of Hartlepool.

It is difficult to know how to deal with the situation. Established hypochromic anaemia may need several months' treatment with iron. Patients with depression may need a long course of antidepressive drugs. Nevertheless, the patient will have to be seen at intervals to check progress, and the prescriptions should cover no more than these intervals. Patients should be encouraged to hand to their doctors or pharmacists all the unused portions of prescriptions, and when there is a death all the drugs left over should be handed in. It would help if doctors would ask for this to be done. Similarly, hospitals could help where death has occurred in hospital by offering to dispose of drugs still at home.

The National Health Service is not likely to benefit financially by the handing back of unused drugs. Apart from administrative difficulties it would hardly be possible to make use of them again, in view of the limited shelf life of many. Some waste is inevitable under any form of service, private or public. There are a large number of drugs marketed with only minor variations. Selling pressure causes them to be prescribed, and for a short time there are runs on this or that drug. If demand fails they may be left on the hands of the retail pharmacist. One pharmacist handed in for disposal 6,328 tablets and capsules, out-of-date stock (these are not included in the collection described above). In few homes are there not bits of this and that put aside in case they might be useful at some time, and the dustbins proclaim the great quantity of waste food from plates and left-overs. But if unwanted drugs were handed in there would not be this frightening load of poisons lying on the shelves.

Summary

A collection of unwanted drugs was made in the Hartlepools area from 13 to 18 March. A total of 43,554 tablets and capsules were handed in, of which 36,242 were identified.

The counting and identification were done mainly by Miss E. Irvine. I should like to thank Dr. H. C. Milligan, Medical Officer of Health for Hartlepool, his staff, the local pharmacists, and the press and T.V. services for their help in the collection. I should like to thank Mr. W. Ryder, hospital group engineer, and his staff for their help in designing and cutting the prototype disc; the pharmacists and pharmaceutical firms for assistance in identification; and the Hartlepool Hospitals Management Committee for the use of a room for counting and identification.

This work was supported by a grant from the Newcastle Regional Hospital Board, which is gratefully acknowledged.

NEW APPLIANCES

Roto-rest

Dr. F. X. KEANE, of the National Medical Rehabilitation Centre, Dun Laoghaire, County Dublin, Eire, writes: The Roto-rest has been designed to introduce automation into the nursing of severely disabled patients. It makes improved nursing care possible which hitherto was not practical or economical, and facilitates medical examination and specific therapy of these patients. This bed is primarily intended for use in the treatment of spinal injuries, with or without the complication of paraplegia or quadriplegia, and also for head injuries and orthopaedic cases. It may also be used to great advantage for the chronic patient at home.

The standard Roto-rest is remarkably simple in construction, and is no longer than the standard hospital bed fitted with skull-traction equipment; it is 3 ft. (91 cm.) overall in width and 8 ft. (244 cm.) in length. In the horizontal position the patient is at a convenient height, being 41 in. (104 cm.) above floor level. This size of bed will take a patient varying in stature from 4 ft. 10 in. to 6 ft. 3 in. (147 to 190 cm.), including the distance required to accommodate conventional skull-traction tongs and special traction assembly.

The bed consists basically of three parts. A ground frame with four braked 6 in. (15 cm.) castors. This frame has two upright pillars on which a U frame rocks longitudinally to provide varying degrees of head and foot inclination. The foot of the U frame may be clamped in bearings on the ground frame at the foot end, and by activating a jack, mounted between the ground frame and this U frame, the U frame may be raised so that the patient can be put in a standing position if desired. The bed proper is pivoted at either end in the U frame, so that rotation about the longitudinal axis is achieved (Figs. 1–3).

The surface of the bed is divided into hatches which may be opened independently. These are situated under the patient's legs, arms, and centrally under his head and neck, thorax, and buttocks. The hatch situated in the thoracic region carries a spring steel section which permits adjustment, so that the lumbar and thoracic spine may be supported or extended at any position along its length (Fig. 4). In place of a conventional mattress plastic-covered removable foam-plastic sections are used. Upright removable members are fitted which extend from the axilla to the foot of the bed, and may be contoured to the individual patient by the surgeon to afford lateral support. Adjustable head, shoulder, knee, and foot supports are also provided. Skull traction is available, from 0 to 56 lb. (25.4 kg.), by a constant-tension spring system, which is concealed within a frame member of the bed. Conventional bedclothes are dispensed with, and an air blower in the foot of the bed may be provided.

The patient is placed on the bed, all parts of which can be adjusted to the surgeon's satisfaction. This usually takes about five to ten minutes. The patient never again has to be manually lifted for the full duration of his treatment. Nursing care may be carried out by one person alone through the

FIG. 1.—The patient is capable of moving his arms freely to hold a book, etc., while the bed is on the automatic turning control.

FIG. 2.—Elevation of foot of bed, showing positioning of patient.

FIG. 3.—Bed elevated to about 45 degrees.

FIG. 4.—Accessibility to patient's thorax, etc., through back of bed.

FIG. 5.—How extension of hip and shoulder is achieved.

hatch system and removable sections of the bed. The functions of the bed are described below in order of their importance:

(1) *Automatic Turning of the Patient.*—The bed may be programmed to carry out turning of the patient through a preselected number of degrees up to 160 as a continuous motion or executing one turn at 10-, 15-, or 30-minute intervals. The optimum speed of rotation has been established at 35 degrees a minute. In the event of electrical failure the patient may be turned by one person without effort through 160 degrees in six seconds. The patient may turn himself through any desired number of degrees and stop the bed in a required position by a press-button provided for his use, and may switch on to "auto control" for hours of sleep. In the event of electrical failure the patient, if he has the use of his arms, may turn the bed manually himself.

(2) Correct alignment of the spinal column and continuous skull traction are provided at all times for the full duration of treatment, even when the bed is working on the auto control.

(3) A continuous venous blood flow, particularly in the lower limbs, is maintained to avoid the complication of venous thrombosis.

(4) A full range of joint movements of the upper and lower limbs can be achieved by the physiotherapist with the patient in the horizontal recumbent position by the use of the hatches, which means that she does not have to turn the patient to complete a full treatment, and gravity may be used to assist in achieving extension of the hip joint (Fig. 5).

(5) The placing of a patient with head or foot raised through 15 degrees is carried out by activating the jack.

(6) The patient may be placed in a standing posture for re-education of the vascular system at 80 degrees with the horizontal, and when in this position his weight is taken on the foot supports.

(7) The Roto-rest may continue to execute automatic turns, and traction may be maintained while operations 4 and 5 are executed.

(8) Toilet care is carried out through the rectal hatch, and continuous catheter drainage, or the use of the Urovac, is facilitated through an opening in the hatch. Reflux of urine into the bladder is discouraged owing to the position of the drainage tube and urine container when the full container is being replaced.

(9) Conventional bedclothes are not used, and the bed is washed and dried at the same time as the patient's bathing is carried out. This avoids all laundry expense and bedmaking, and tends towards better hygiene in the ward. Disposable paper sheets are placed only under the patient's head, thorax, and buttocks without manual movement of him, as all areas of the body are easily accessible for this purpose. Conventional bedclothes may be used as a top cover if desired, and if so are held by clips.

(10) The patient is retained in the bed by the removable shoulder and knee clamps only, thus avoiding any embarrassment of respiration. These clamps also serve to maintain proper posture of the lower limbs and control involuntary spastic movements.

(11) The clamps prevent a confused or agitated patient injuring himself by movement or climbing, or by falling out of bed.

(12) A patient, while secure in bed, is able to move his hands and arms freely to feed himself, read, etc., but owing to the design of the shoulder clamps he cannot interfere with the head-traction assembly.

(13) While the patient has a desirable freedom of movement of his upper limbs, he is prevented from reaching and removing his catheter, if one is in situ, owing to the height of the side-supporting members.

(14) Ventilation of the skin is achieved as the bed is usually turning in continuous motion, thus avoiding constant skin contact with the weight-bearing surfaces.

(15) Control of the patient's temperature is possible by a variable-speed air blower situated in the foot of the bed. As the patient turns, practically all areas of his body become exposed to the air-flow which it produces, thus avoiding the use of hypothermic drugs, ice drips, etc.

(16) Continuous intravenous infusion is more easily maintained, because accidents caused by handling of the patient for turning are obviated, and the tendency to thrombosis in the veins is reduced.

(17) A red warning light indicates to the nursing staff that the bed is in motion. If this light is not visible the cause must be investigated. If desired, a no-volt alarm may be fitted which will alert the staff or awaken the patient if an electrical failure results; this is important, particularly where the bed is intended for home use.

(18) Variable abduction of the patient's legs is possible to enhance the venous return when rotating, as each leg is alternately elevated and depressed.

(19) Facility for positioning *x*-ray plates is incorporated so that films may be taken in any posture of the head, neck, and trunk without lifting the patient.

(20) Spring leg traction may be fitted up for treatment of fractures of lower limbs.

ADVANTAGES FOUND ON CLINICAL TRIAL

The medical officer's time is saved, as any part of the patient's body is immediately accessible for examination and treatment. The physiotherapist can carry out a full range of joint movement of the limbs while the patient is in the recumbent position, and can make use of gravity to effect extension of the hip joints. Patients can be put in any posture for chest physiotherapy, etc. Nursing is reduced to bed-bathing, toilet care, and administering drugs. Bed-making is not required. Bedsores do not occur.

Venous thrombosis in the lower limbs has not occurred in any patient nursed in the bed so far. Flexion contractures from spasticity are prevented. Clinical trial has shown that practical immobilization of spinal fracture is achieved and correct alignment traction is possible during continuous automatic turning. Marked relief of pain at fracture site has been observed. Chest complications in susceptible patients have not appeared, and patients who already have contracted chest infections improved rapidly when put on the bed. This is an outstanding advantage to paraplegics and quadriplegics, who may suffer greatly from respiratory embarrassment.

It has been noted, when carrying out intermittent catheterization, that sediment has not been allowed to form, or, if so, is minimal. Prolonged intravenous infusion has been easier to maintain, as clotting tendency and accidents are reduced. Urinary reflux cannot occur, as the orderly cannot lift the bottle higher than the patient because the drainage tube comes out through the hatch under the middle of the bed, and not over the side, which is the case in standard practice. It has been noted in some patients that constipation and nausea have set in when they were transferred to conventional beds. Noise in the ward at night-time caused by personnel is eliminated, and the patients may have an undisturbed night's rest.

At a turning speed of 35 degrees a minute the patient is unaware of the turning motion, and yet it is fast enough to ensure adequate blood flow in the limbs. Another minor advantage is that the patient does not suffer from sore ears, which may be a problem on conventional beds. He also has a changing field of vision as he turns. Embarrassment to him is avoided when having to use a bed-pan, as stripping of the bed is not required. There is a possibility that with this bed a device could be used to handle faecal incontinence; this is under consideration.

FINANCIAL ASPECT

The use of the bed has reduced the doctor's, physiotherapist's, and nurse's time considerably in carrying out their treatments. It takes 35 minutes for one nurse to wash and dry the patient and bed, which is carried out once in 24 hours. Apart from this the nurse has to attend only to the administration of drugs and toilet care. No bed-making is necessary. Orderlies for turning and lifting the patients are entirely dispensed with during treatment. Since virtually no laundry is required, each bed has represented a saving of 42s. a week in this respect. Cost of drugs is also reduced owing to the reduction in chest complications. The bed is powered by a single one-tenth h.p. motor. The cost of running the motor is equivalent to that of a 50-watt bulb. The bed is extremely robust in construction and requires no maintenance. Independent sections replace the normal mattress; therefore at the most only the three sections under the patient's trunk may require replacement at intervals of about two years, which is an extra saving.

Proposed Legislation on Drugs

Last week the Government issued a White Paper (Cmnd. 3395, H.M.S.O., London, 1s. 9d.) on forthcoming legislation on the safety, quality, and description of drugs and medicines. A summary of the proposals is printed below. (See leader p. 689).

Reasons for Legislation

The White Paper reviews the action taken by the Government in 1962 as a result of the disquiet caused by the teratogenetic actions of thalidomide. A committee under the chairmanship of Lord Cohen of Birkenhead recommended that legislation on the safety and efficacy of drugs was urgently required and that meantime a voluntary system should be set up to screen drugs for toxicity and adverse reactions. This led to the appointment of the Committee on Safety of Drugs under the chairmanship of Sir Derrick Dunlop.

The Paper goes on, "The voluntary system has had the full support of the pharmaceutical industry and the medical and pharmaceutical professions, but the Government considers that the provision of statutory backing for these safeguards would give greater reassurance and should not be further delayed," and draws attention to the recommendation made by the Committee on Safety of Drugs in 1965 that its arrangements should be made permanent by legislation.

The Paper points out that controls similar to those which it proposes have already been introduced in Commonwealth countries, the U.S.A., and elsewhere, and that in the event of Britain joining the European Economic Community legislation of this kind may become necessary.

The responsibility for the proposed controls will lie with the Health and Agriculture Ministers of the United Kingdom. The Home Office will no longer be concerned with medicinal aspects of substances in the poisons lists.

Medicines Commission

A commission, known as the Medicines Commission, is to be appointed by the Ministers after consultation with professional bodies representing medicine, dentistry, and veterinary surgery. The Commission will advise the Ministers on matters of policy and make recommendations about the terms of reference of expert committees. The Commission will also act as an appeal body for applicants for licences (see below).

The Commission will take over from the General Medical Council the responsibility for the production of the *British Pharmacopoeia*. It will not deal with non-medical aspects of substances controlled as poisons.

The new measures will control drugs and preparations for use in diagnosis, treatment, and prevention of ailments in men and animals, or in modifying physiological functions.

They will also control medical devices having a mechanical or physical action, including shunts, valves, pacemakers, syringes, catheters, and dressings.

The controls will not automatically apply to substances marketed for non-medical use, such as cosmetics or disinfectants; but the Ministers will have power to list substances of this kind as subject to control.

Licensing

A licence, for which there will be a fee, will be required for the marketing, importation, or manufacture of or wholesale dealing in drugs, with appropriate requirements for each activity, and in the case of sale or supply for the purpose of clinical or field trial a certificate or some similar form of authority will be required, in order to ensure that appropriate toxicity testing has taken place before the trial begins.

A manufacturing licence will, however, not be required by a doctor or dentist to make up a preparation for one of his patients.

The particulars to be supplied to the licensing authority in support of applications for marketing and importing licences, or for clinical or field trial certificates, are expected to be on the lines of those now requested by the Committee on Safety of Drugs. Conditions of manufacture, storage, and distribution will also be considered. Temporary provision will be made for existing drugs to be marketed without licence until they can be brought into the scheme.

A licence may be refused, revoked, or suspended if the Minister is advised by the Commission or the appropriate expert committee that the drug no longer conforms with the requirements for safety or efficacy imposed at the time that the licence was given. Provision is made for appeal to the Commission against revocation of a licence or refusal to grant one. There is also a right to be heard by the licensing authority and to appeal to the High Court on a point of law.

Retail sale of drugs to the public will, with some exceptions, be limited to registered pharmacies. The exceptions will permit prepacked drugs for human use listed by the Ministers for general sale to be sold at any shop. Doctors and dentists will be able to sell or supply drugs to their patients or to a person having the care of such patients.

Labelling and Advertising

The sale, supply, or possession of any drug (including samples) bearing a label which falsely describes the drug or is likely to mislead as to its nature, substance, quality, effects, or the purposes for which it is intended to be used or ought not to be used will be prohibited. Similar provisions will apply to any leaflet intended to accompany a drug.

The publication, or display by any means, including radio or television, of advertisements which falsely describe a drug or are likely to mislead will be prohibited.

The Ministers will be able to make regulations specifying drugs or classes of drugs all advertising of which will (subject to stated exceptions) be prohibited.

Requirements could also be made, the Paper states, with respect to the content, format, and manner of presentation of advertisements for drugs, to ensure that those to whom the advertisement is directed are given adequate information about the drug.

Before a drug is promoted to a doctor, dentist, or veterinarian by direct mailing or by medical representatives he must be provided by the promoter within a specified period beforehand with an objective summary, probably in the form of a standard size of data sheet, of essential reference particulars about the drug conforming to provisions in the licence, and the promotional matter will have to be consistent with these.

Consultation

The Paper concludes by stating that before making regulations (other than those broadly reproducing existing regulations) the Ministers will be obliged to consult such organizations as appear to them appropriate as being representative of the interests substantially affected, and that it is the Government's expectation, judging by the general tenor of the observations received on the earlier proposals, that legislation on the lines now to be introduced will command widespread support.

Correspondence

Letters to the Editor should not exceed 500 words.

Consultants' Views of General Practitioners

Sir,—Mr. Cecil W. Flemming writes (26 August, p. 561) that my statement in a General Medical Services Committee debate "Teaching hospital consultants saw only the worst side of general practice; they did not see the successes" (*Supplement*, 12 August, p. 115) is in his experience complete nonsense. In his experience no doubt it was so, but perhaps my words could be described as an overstatement provoked in the heat of debate by an exposition of the consultants' case against some general practitioners. The most provoking sentence was "there were many general practitioners who were only too delighted to dump the whole of their work on to the hospital service."

Sadly there seems to be a great lack of contact and understanding between general practitioners and consultants in these days. Pre-war, I am told, most consultants became so after a spell in general practice and continued their contacts with general practitioners in consultations. Consequently, each group understood each other's problems and had respect for one another. Nowadays the vast majority of consultants have done no general practice in the Health Service and apart from domiciliary consultations have very little contact with those who give primary medical care.

Part of the trouble arises, as I tried to say in the debate, from the fact that in hospital outpatients in general and in medical outpatients in particular general practitioners' mistakes are likely to stick out like sore thumbs. Those patients whose problems have been fully coped with by the family doctor will never reach outpatients and the consultant is never aware of them. As a result of seeing an unbalanced picture he may well tend to be critical of general practice in his dealings with his juniors. As was said earlier in the same debate "students were getting the 'vitriolic drip, drip' from consultants who continually drew attention to what was wrong with general practice."

Measures are needed to resolve these misunderstandings. Perhaps the most effective would be to make a period of general practice compulsory for all doctors and for refresher courses to take place at regular intervals.—I am, etc.,

B. D. Morgan Williams.

Claverdon, Warwick.

Sir,—Mr. Cecil W. Flemming (26 August, p. 561) describes as nonsense the remark of Dr. B. D. Morgan Williams to the effect that "teaching-hospital consultants saw only the worst side of general practice; they did not see the successes." Perhaps the remark would be more literally true if the words "comment on" were substituted for "saw" and "see." Mr. Flemming thinks the remark is to be deplored, but, as reported, it seems to me pretty harmless. However, if he wants a remark to which the term deplorable is flattering, he should look up again the same *Supplement* (12 August, p. 114), where Dr. H. Glyn Jones is reported to have said that "there were many general practitioners who were only too delighted to dump the whole of their work on to the hospital service."

It is an unfortunate fact of modern medical life that teaching hospitals—and indeed most non-teaching hospitals—indoctrinate students and young graduates with the idea that general practitioners are largely skrimshanking medical morons. This is one reason why young doctors opt for hospital work or emigrate instead of going into general practice in the N.H.S. Other reasons are that these young men can see for themselves what a relatively important and privileged life is led by senior hospital staff in the N.H.S., and they are very conscious of the excessive moaning about their lot by a small proportion of general practitioners. These are not the only reasons for the unpopularity of general practice but they are important ones.

Most doctors, whether in specialist—modern euphemism consultant—or general practice will deplore and question the motive of blanket attacks by members of one section of the profession or another. Criticisms should be made face to face or by personal letter in individual cases and not, as is too frequently done, by general innuendo; so far general practitioners have specialized in turning the other cheek in spite of a superabundance of material for attack by them. Perhaps the sturdy defence of general practice by Dr. H. N. Rose and Dr. B. D. Morgan Williams is the first sign that the worm is beginning to turn.—I am, etc.,

Bath.

W. B. S. Crawford.

Place of the Mentally Retarded

Sir,—I was dismayed to read in your leading article, "Place of the Mentally Retarded" (2 September, p. 567), that you advocate that no special search should be made to "ascertain" or to make special provision for the large proportion of mentally subnormals who are not known to hospitals or local authorities, because there is not enough provision for those who are already known. As at the present time already 77 inborn errors of metabolism are known and an ever-increasing number of these are becoming treatable, it would be disastrous if no arrangements were made for systematic screening and for regular follow-up treatment of the afflicted.

Furthermore, a number of mentally retarded of all ages have somatic handicaps which can be treated, and the expert assessment of their training and employment potential would increase their usefulness to society. It is therefore of the utmost importance that a special search should be undertaken for the half a million subnormals in our midst.—I am, etc.,

Rudolph Payne.

Little Plumstead Hospital,
Norwich, Norfolk.

Sir,—Your leading article (2 September, p. 567) gives an interesting review of the position of the mentally retarded in hospital in parts of England, but in some respects the figures quoted are very different from this area in Scotland.

In the period 1959 to 1964 the proportion of feeble-minded patients in our hospital group of 1,731 patients had fallen from 41.2% to 33.9%.[1] In 1964 the average I.Q. for the feeble-minded females was 50 on the Terman–Merrill L–M Scale (males 57.5).[1] Thus two-thirds of all the patients were in the imbecile and idiot groups with an I.Q. below 45. The proportion who could be discharged for useful work in the community is much less than you suggest, but I would heartily endorse your remarks about the dearth of open hostels.—I am, etc.,

D. Primrose.

Lennox Castle,

S.T.P. and the Law

Sir,—The Food and Drug Administration has now positively identified S.T.P. as 4-methyl-2,5-dimethoxy alpha-methyl phenylethylamine,[1] and so has confirmed the first of the speculations in your leading article (2 September, p. 570). This substance, also called D.O.M., was developed by the Dow Chemical Co., which published no information about it, made no supplies of it available, and did not ask for permission to conduct clinical investigations with it. The mode of its entry into illegal channels is unclear.

On facts, such as they are, you were helpful; on positive suggestions for action much less so. It is inadequate, if not meaningless, to suggest that the statutory measures relating to such substances be made more flexible. Laws must be workable as well as flexible, and it is abundantly clear that the existing law on soft drugs is neither, while the law on hard drugs may well soon cease to be both. Young people are beginning to try any drug. I understand that antidepressives, tranquillizers, and appetite suppressants are already available in the usual quarters. Is the law to be sufficiently "flexible" for it to be an offence to possess any centrally active drugs without a prescription? Abuse of other therapeutic substances not primarily used for their mind-altering properties, which for obvious reasons I shall not name, may well follow, since they certainly can induce sensory or perceptual changes. Will a flexible "law" forbid the possession of any drugs at all without a prescription? There might be something to be said for this, whereas for the present policy of changing the law, or designating secret and in fact non-existent treatment centres, there is absolutely nothing to be said.

It is time to examine comprehensively the attitude of our society to the flood of new chemicals that it is itself calling into existence. What new kinds of drug action do we need? If we will only specify them, our inventive and resourceful pharmaceutical industry is very likely to produce them. Meanwhile, it is apparent that we need hallucinogens, for they are what we are getting. Why? We need scientific answers, not guesses themselves based on fantasies. Perhaps we should begin by asking that our legislators recognize this as the kind of question that matters, and that not until we have tried to answer it scientifically can there be any reasonable basis for changing the law, whether in the direction of increased flexibility or the reverse.—I am, etc.,

Experiments on Man

SIR,—I hope that Dr. M. H. Pappworth, whose clinical ethics, to judge from his book and now from his letter (2 September, p. 616), appear to him to be so impeccable, will not lose time in writing his code for clinical investigation. He must also list the punishments that are, as he pleads, to be "meted out to those who flagrantly disregard" him. Presumably the penalty for an unnecessary I.V.P. will be less than for an unnecessary retrograde pyelogram. It will be interesting to see how he defines the precise indications for such things. We shall certainly all need a large reference book on our clinic desks. Will the penalties be fines graded by offence and income? Who will exact them?

Life will be simpler in some ways, since no new methods could get on to the list, for all are potentially risky and of unproved value when first done, so none of us will have to bother with any advance of techniques.

Does Dr. Pappworth really believe that his fantasy is preferable to the judgement of senior members of a profession whose ethical standards have always been its pride? Let us have no more of this petty nonsense, and let men of knowledge and probity ensure that the difficult ethical problems of clinical research are handled helpfully and sensibly, to ensure that the evil things to which Dr. Pappworth has rightly drawn our attention are stopped, while the stream of medical research flows on unimpeded.—I am, etc.,

London S.W.10. CHARLES FLETCHER

Training for Obstetrics and Gynaecology

SIR,—Your leading article "Training for Obstetrics and Gynaecology" (2 September, p. 568) seems to have failed to grasp the real meaning of what the select committee of the Royal College of Obstetricians and Gynaecologists was trying to do. The objects of the report are laid out in the last paragraph of the foreword[1] and I feel that the R.C.O.G. should have been given credit for having the courage to initiate such an investigation. The results of a similar investigation by other bodies might make interesting reading.

In the leading article it is stated: "If they had had enthusiasm, dreamed dreams, and seen visions, the medical world would not have such a drab view of what obstetrics and gynaecology is." One would have thought that this is exactly what the founders of the R.C.O.G. were doing, and what their successors have been doing for years with such excellent results. The R.C.O.G. pioneered training before examination, and much of what has been common practice in the College examinations is now being copied by other examining bodies.

The College, however, is not content to stand still, and the Report is an attempt to initiate the improvements deemed necessary to meet the changed conditions of today and the challenge of the future.—I am, etc.,

C. H. G. MACAFEE.

Summer and Death from Neuroblastoma

SIR,—Dr. J. A. H. Lee (13 May, p. 404) has reported that neuroblastoma deaths were more common in summer than in winter among children under 15 years of age in England and Wales in 1958–64; the quarterly totals starting in January were 84, 112, 105, and 84 (total 385). In a similar but much larger study (n=1,362) of neuroblastoma deaths among white children in the U.S.A., 1960–4, we have found no corresponding seasonal variation over the entire country or for the colder north-eastern and north-central States (see Table).

Numbers of Neuroblastoma Deaths Among U.S. Whites Under 15 *Years of Age by Season,* 1960–4

Area	Season of Death, 1960–64				P*
	Jan.–Mar.	Apr.–June	July–Sept.	Oct.–Dec.	
Total U.S. ..	339	328	346	349	0·14
N. East and N. Central ..	203	187	194	201	0·15
Other ..	136	141	152	148	0·25

* Probability that annual variation was due to chance based on χ^2 value, 1 d.f., in a one-tailed test.[1]

An adaptation of the Ederer–Myers–Mantel statistical procedure[1] for detecting clusters of rare events was applied to three- and four-month seasons and to months within seasons, beginning alternately in January, February, March, or April. Only 3 of the 42 tests performed were significant at the 5% level, which is consistent with normal expectation. Study was then made of neuroblastoma mortality by State of usual residence, including the District of Columbia, and five one-year periods. In a summation across all 255 time-space intervals no excessive cluttering was found. Summation across the nine geographical divisions of the United States, however, revealed clustering significant at the 5% level, an effect due to an excess of neuroblastoma deaths in certain years in the middle Atlantic, west-south-central, and mountain divisions. To illustrate, the annual totals for the mountain States were 7, 9, 23, 9, and 13. When the States were considered individually only Texas (a west-south-central State) displayed year-to-year fluctuations which were significantly different from normal expectation. No explanation for this variability could be found.

Finally, the sex ratio (M/F) for neuroblastoma deaths under 5 years of age decreased progressively from 1.7 in 1960 to 1.1 in 1964, a change which was statistically significant at the 2% level. Thus, though neuroblastoma deaths did not vary seasonally in the United States, there appeared to be other irregularities in the distribution of the disease in time and space. A fuller description of our observations will be published elsewhere.—We are, etc.,

Speed Control

SIR,—Speed does not necessarily cause accidents, but "unrecognized" speed and high speed by any other than the comparatively few highly experienced drivers does. The disproportionately high serious injury and fatality rates in teenage drivers are evidence of this. When crashes occur at speed the injuries are correspondingly more severe and multiple. On motorways the accident rates are, by comparison, lower, but the fatality rates significantly higher, and 50% of those who die do so before reaching hospital, and this is double the early death rates on other roads.

From research experience, one of the more difficult assessments to make is the speed of a car at the time of its crash. The estimates of roadside witnesses are notoriously fallacious, but, much more important, so are those who have the speedometer in front of them. This is not so much a matter of speedometer design, though some are better than others. Drivers are reluctant to take their eyes off the road, and they give their next priority to their rear view and side mirrors with occasional glances only at the speedometer. Then they may be horrified, surprised, or pleasantly conditioned by such things as the sound of a police siren, the recognition of having been caught in a radar trap, or the considerable difficulties experienced in negotiating a roundabout after leaving a motorway, or in coping with any dangerous situation.

There are two devices, both American, that help in such situations. One is a radar detector that slips on the sun visor and peers through the windscreen, useful to drivers who have fully developed the art of police detection, and perfectly legal in the States, but frowned upon in Britain. The other should be more widely known, though not yet available in Britain. It allows the driver to give his full attention to the road and its environment and relieves him of the impossible task of judging his speed by instinct. Any desired speed is set by the flick of a switch on the steering column from a chosen speedometer reading. The foot is taken away from the accelerator pedal and placed over the brake pedal. The chosen speed is then precisely maintained apart from easing off slightly up a gradient and gaining an insignificant amount when going downhill. The set speed can be instantly overriden by pressure on the accelerator pedal—a useful aid when entering a road with a higher speed limit—and a downward flick of the switch again sets the device to conform to that limit. The merest touch of the brake or clutch pedals puts the device out of action.

After four months use of this speed control no faults have developed, but it has given me a new sense of speed and safety. The instinctive feeling at first was of moving too slowly; a glance at the speedometer corrected that impression. Next I developed a greater confidence in judging braking distance and eliminated my hitherto frequent use of accelerator and brake pedals, which resulted in a smoother performance of my car and economies in engine and tyre wear and in petrol consumption.

The commonly held objections to speed limits may rest in great part on the inability of most drivers to conform to them. Something more than a speedometer would seem essential with the smooth performance of modern cars on good road surfaces and the crowded traffic conditions. The available research evidence on speed indicates that there is a need for minimal as well as maximal speed limits—the former has particular reference to heavy freight transporters on open roads.

It is estimated that the device would sell in Britain at around the price of a car's radio, and one wonders why manufacturers are so hesitant to offer it to the public. Perhaps it is yet another example of the repetition of the old dilemma—research evidence was not good enough in the United States for voluntary action by the Detroit manufacturers on safer car design. Finally, it became a matter for legislation. It seems that safer car design is on the way in, and the indications are that in future battles for car sales worthwhile safety features will outsell useless stylists' gimmicks.—I am, etc.,

Hetacillin and Ampicillin

SIR,—With reference to a recent letter entitled "Hetacillin and Ampicillin" (5 August, p. 367) we would like to draw attention to further independent absorption and excretion studies of hetacillin and ampicillin. In a series of studies on the stability, absorption, and excretion of hetacillin[1] the following results were obtained.

Hetacillin, which is a condensation product of ampicillin with acetone, is rapidly hydrolysed in aqueous solution to ampicillin and acetone with a half-life time of about 30 minutes between pH 3 and 8.

The absorption and excretion characteristics of hetacillin were defined in comparison with ampicillin by crossover studies. Hetacillin gave marginally higher blood concentrations than ampicillin at 6 and 8 hours. In this respect our results are in agreement with those of Bunn *et al.*[2] and Kirby *et al.*[3] However, the peak level of hetacillin was only about half that of ampicillin. Furthermore, the urinary excretion of hetacillin was again only about half that of ampicillin, indicating poorer absorption of hetacillin.

These studies were carried out on hetacillin prepared by Bristol and ampicillin prepared by Beecham, both products obtained commercially. Our results are thus in much better agreement with those reported by the Beecham investigators (24 June, p. 804) and also with those of Ridley[4] than with those of the two American groups.[2 3]—I am, etc.,

Hypernatraemic Dehydration

SIR,—Dr. H. Simpson and Dr. J. O'Duffy's warning about overstrong infant feeds (26 August, p. 536) is timely. Hypernatraemia may also occur in small babies on normal feeds if extra water is not given when they are hot, feverish, or panting; and clinical dehydration is not necessarily present.

A two-week-old boy was admitted because of a staphylococcal infection of the scalp. This responded well to cloxacillin, but after a heat wave shortly before discharge he became torpid with no specific signs or weight change. His cerebrospinal fluid contained no cells and a normal amount of glucose. The serum sodium concentration was 212 mEq/l., chloride 180 and urea level 102 mg./100 ml.; potassium and bicarbonate levels were normal. He recovered uneventfully on half strength feeds and a slow infusion of half normal saline (77 mEq/l.). Three years ago a month-old baby was admitted in a similar state and is well.

The greatest peril of hypernatraemia is its treatment. If the osmotic pressure of the cells or of the cerebrospinal fluid lags behind that of the blood because of too rapid treatment with dilute liquid, fits or anuria from cerebral or renal oedema may occur, and demand hypertonic mannitol or frusemide. I have discussed this elsewhere in a different setting.[1] —I am, etc.,

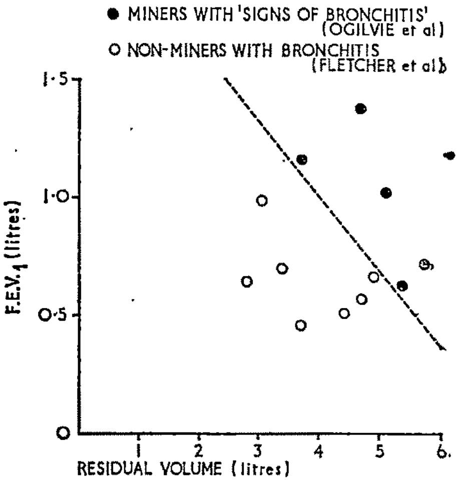
Overinflation of the Lungs of Coal Miners

SIR,—Drs. G. B. Field and J. E. Cotes (19 August, p. 493) have compared five of our seven miners having "signs of bronchitis" with six of the ten without such signs. They apparently conclude that disability is mainly due to chronic non-industrial lung disease in the first group and compensation neurosis in the second. The remaining six miners are also placed in one or other of these two categories.

The argument presented in favour of non-industrial lung disease as the cause of the increased lung volumes in the five miners with signs of bronchitis depends upon their similarity to Fletcher's patients with chronic bronchitis.[1] This resemblance is superficial, for when they are actually compared with Fletcher's patients the five still display the pattern shown by the group of miners as a whole—that is, an increase in lung volume disproportionate to the degree of airways obstruction (see Fig.). A separation of the two groups similar to that shown in the Figure can also be obtained when the five bronchitic miners are compared with our own patients having non-industrial lung disease, and when F.R.C. or T.L.C. is substituted for R.V. The distinction is even more definite when (as seems reasonable) the other two miners with signs of bronchitis are also included.



Forced expiratory volume (1 second) plotted against residual volume for miners "with signs of bronchitis" (Ogilvie *et al.*[5]) and non-miners with bronchitis (Fletcher *et al.*)

The argument presented in favour of compensation neurosis as a cause of the large residual volumes in the six "non-bronchitic" miners rests largely upon their "remarkably low expiratory reserve volumes"—that is, failure to expel the vital capacity. But in fact the expiratory reserve volumes are "remarkably" low only by the prediction formula of Cotes and Meade.[2] The mean E.R.V. of these six miners is 79% of the value obtained in our normal subjects, 73% of the value predicted from the formula of Needham *et al.*,[3] but only 46% according to the formula of Cotes and Meade. (Baldwin *et al.*[4] do not have a formula for E.R.V.) Drs. Field and Cotes claim that the Cotes and Meade formula is in some way "more appropriate" than the formula of Baldwin

	Cotes and Meade	Baldwin *et al.*
Vital capacity	90%	100%
Vital capacity	90%	100%
Residual volume ..	77%	106%
Total lung capacity ..	80%	102%
Expiratory reserve volume	60%	82%*

The lung volumes of the normal subjects reported by Ogilvie *et al.*[5] shown as percentage of predicted normal according to the formulae of Cotes and Meade and of Baldwin *et al.*

* E.R.V. predicted from the formula of Needham *et al.* (not available in Baldwin's formula).

et al. which we used. It may well be more appropriate to the inhabitants of South Wales (upon whom it was presumably based), but it compares unfavourably with Baldwin's formula when applied to the healthy Lancastrians who served as our normal controls.

It is on this evidence that Drs. Field and Cotes have attributed the disability of our miners either to non-industrial lung disease or to psychological factors. In doing so they appear to have ignored one of their own subgroups of our miners (those with neither *x*-ray changes nor signs of bronchitis). As a group these men have relatively little evidence of airways obstruction, but their average total lung capacity is larger than in either of the other groups considered by the writers and nearly 2½ litres greater than for our normal subjects. This cannot be attributed to bronchitis, in which the total lung capacity is usually normal even when there is gross airways obstruction.[1] Nor indeed to psychological factors—for what man, by taking thought, can add 2½ litres to his total lung capacity ?

We agree (and indeed admitted in our paper)[5] that we have not made a "good case" for the existence of focal emphysema among our miners because, to achieve this, we must wait until they are dead. What we do claim to have shown is that the great majority of the miners have a degree of lung overinflation which is greater in relation to airways obstruction than in any published series of patients with chronic non-industrial lung disease—including our own.—We are, etc.,

Oxygen Therapy Equipment

SIR,—In your leading article (26 August, p. 511) you refer to our paper,[1] and state that we found that the M.C. mask had a significant dead space. However, you do not make clear what you consider to be a significant dead space, and, while we reported a small one, we did not say that this was significant. Testing the M.C. mask, Bethune and Collis[2] found that the subject's physiological dead space increased by 75 ml. breathing oxygen at 2 l./min.

In our paper we showed that, while breathing room air through the vents in the M.C. mask, with no oxygen flowing in, the CO_2 concentration inside the mouth fell to zero between each respiration as rapidly as when the subject was wearing no mask. We therefore consider it unlikely that the small dead space is of clinical significance.

The Edinburgh mask was not tested for dead space, and so we do not think comparisons should be made with this. In their original description of the Edinburgh mask the authors[3] described it as being designed to give controlled oxygen at low concentrations (23–40%) and for this reason we were surprised that it was recommended by you as being the best mask for general purposes.—We are, etc.,

Advertising Arthritis

SIR,—With what justification does the Arthritis and Rheumatism Council put up posters with the headline "Arthritis Means Crippling, Pain" ? Is not the *raison d'être* of rheumatology to refute this sort of statement, or should doctors now use the word "arthritis" with great circumspection in view of its new sinister connotation "crippling pain" ?—We are, etc.,

Oculogyric Crises Due to Phenothiazines

SIR,—Recent correspondence on the subject of oculogyric crises due to phenothiazines (22 July, p. 241, and 12 August, p. 438) prompts us to report two recent cases of acute extrapyrimidal attacks in which oculogyric crises were a prominent feature. Both patients were children who had been prescribed dehydrobenzperidine (Droperidol) as sedation to permit positioning for radiotherapy.

The first case was a 6-year-old girl under treatment for a pontine glioma which had caused a spastic left hemiparesis. She was given dehydrobenzperidine 7.5 mg. orally each day one hour before treatment. Two minor episodes of spasm were witnessed by nurses (approximately six hours after administration) during the first two weeks of treatment. A third episode was witnessed by one of us and the details recorded. It occurred three and a half hours after ingestion, and consisted of generalized rigidity of the trunk and limbs, the neck being extended and the arms flexed. The paretic leg became acutely hyperextended and the unaffected leg was flexed. There was also a fine tremor of the limbs. The eyes were rolled upwards and maintained in a position of elevation, and this condition persisted for 30 minutes before gradually subsiding.

The second case, a 2-year-old girl with acute lymphoblastic leukaemia in complete haematological remission, was given a course of prophylactic radiotherapy to the brain. Dehydrobenzperidine 2.5 mg. was given by mouth, and three hours later her eyes rolled upwards and the neck became hyperextended. The upper limbs were rigidly extended and there was a fine tremor of the hands. These attacks came in spasms for the next three hours. Next day a similar but more severe episode was repeated after the same dose of dehydrobenzperidine.

Acute parkinsonism may occur with large doses of dehydrobenzperidine. In both these cases, however, the doses used were within the recommended range, and it may be that the threshold is lowered by pre-existing brain disease.

We are grateful to Dr. P. E. Thompson Hancock and Dr. H. J. Bloom for allowing us to publish these cases.

Multiple Sclerosis in South Africa

SIR,—Dr. G. Dean's important study (17 June, p. 724) of multiple sclerosis (M.S.) in South Africa has been long awaited. Especially noteworthy are the differential frequencies by the country of origin of the patients. The crude prevalence rates for probable M.S. for all groups except the English-speaking natives are within the ranges expected for their homelands in accordance with the general distribution of M.S. within three broad frequency zones: high (30–60/100,000) in Europe from Switzerland northward, medium (circa 10) in southern Europe, and low (0–4) in Asia and Africa ; with similar high and medium zones in the United States and Canada.[1]

Thus immigrants retain the M.S. prevalence of their land of origin when moving into low frequency areas, as is also attested to by the studies of Alter in Israel,[2] Saint (recalculated) in Australia,[3] and Moffie in the Dutch Antilles,[4] although their progeny in these other studies at least acquire the disease at the rate appropriate to their new home. This certainly bespeaks an exogenous disease rather than one genetically determined.

Since there is some evidence[5 6] that the critical period in the lives of M.S. patients may be that up to about age 15, it would be most helpful if, for the 72 Europeans who first developed symptoms in South Africa, Dr. Dean could provide us with a table listing the ages at immigration, at onset of symptoms, and at prevalence day. This might provide further information on the hypothetical "incubation" or latent period[5 7] between presumed disease-onset and symptom-onset.

The English-speaking natives of South Africa showed a relatively high prevalence rate of 11 M.S. per 100,000 population. Dr. Dean noted that 46 of these 101 individuals had visited Europe before prevalence day, while 41 controls "matched by sex, birthplace, language, and age group, and with the same birthplace of parents, had visited Europe." I believe the fallacy here lies in matching on variables related to the variable in question. Birthplace, language, and birthplace of parents would all seem related to the chances of a person visiting Europe, especially in childhood. Dr. Dean *did* note that 40 of the 101 (twice expectation) had parents both of whom were born in Europe, and 22 had one such parent. Indeed, it may not be possible to devise a proper control group here, but this need not militate against the attempt to measure age and duration of visits and the period to clinical onset in the patients. That people pass through an endemic area unscathed does not lessen validity of considering those who do become ill after such a visit. If we can assume that most or all of these 46 travellers had been to Europe before symptoms began, as well as before prevalence day, there would then be left some 55 English-speaking homebound natives of South Africa to provide a prevalence of about 6 per 100,000, not too dissimilar from the rate of 3 found for the Afrikaners.

Dr. Dean's hypothesis, which is also Poskanzer's,[8] is that early exposure to infection in low risk areas prevents the later development of M.S. If this were true, however, the "unexposed" immigrants should show a much higher attack rate than is found in their native lands, which seems not to be the case in Australia, Dutch Antilles, Israel, or South Africa. Further, the native-born English-speaking South Africans, as well as the Israelis, are recent arrivals, and from neither land do the current prevalence studies indicate any appreciable rate of M.S. in the parents of the subjects. Thus the evidence suggests that M.S. is "caught" in the high risk areas and brought by the migrants in a latent form into these low risk regions which provide such an invaluable human laboratory for M.S. What is the latent period can perhaps be better defined from the points raised here with the data available to Dr. Dean.—I am, etc.,

Early Discharge of Maternity Patients

SIR,—The leading article and papers on the early discharge of maternity patients (26 August, pp. 508, 517, and 520) contained no reference to the importance of restoring the mother who has a young family to her home as soon as possible. The separation of a child for even a few days from its mother can be very traumatic indeed, especially when it coincides with the arrival of a sibling. It is made even more traumatic by the refusal of maternity hospitals to allow children to visit their mothers even when their hospital stay is prolonged. I feel sure that most family doctors would agree that no mother should be retained in hospital for more than 48 hours unless she is a primipara or requires medical and nursing care not available at home.—I am, etc.,

Hornchurch,
Essex.

S. E. BROWNE.

SIR,—The first intimation I usually receive that a patient has been discharged from hospital within two or three days of delivery (26 August, pp. 508 and 517) is an urgent demand for "pills to stop the milk." The patient has usually had an oestrogen for this purpose before leaving hospital, but has no idea of the dose or preparation, nor does the discharge letter give the information, even if it arrives as soon as the anxious friend or relative. It is difficult to assess what quantity of oestrogen to use under these circumstances, and I suggest it would be safer and more economical for each patient to be given the balance of her course of tablets with appropriate instructions on leaving hospital.

Very few patients breast-feed their babies in South Wales, and nearly all believe they must have pills "to stop the milk." A doctor I know gets very good results and no fear of side-effects by giving a placebo, but even this might lead to an oestrogen withdrawal haemorrhage.—I am, etc.,

Port Talbot,
Glamorgan.

R. S. SAXTON.

Chest Pain After Infarction

SIR,—I have read with interest your leader on "Chest Pain After Infarction" (5 August, p. 321), and the article by Professor R. R. H. Lovell and Dr. A. Verghese (same issue, p. 327).

In my opinion the mechanism which causes these pains without any controllable organic lesion is the same as I have described elsewhere.[1] There is anguished fixation of attention upon organs or functions which were the localization of a serious disease suffered by the same patient or by other people closely connected with him. Pain and other somatic complaints are not seldom signs of a libidinous concentration on certain organs. This raising to the first plane of consciousness is a defensive mechanism for an early detection of possible alterations, and, as in somatic medicine, is by itself the cause of symptoms. In Spanish colloquial language "alzaprimar" means to raise the value of something, so that nobody will pay this price and the seller will be hurt.—I am, etc.,

Changed Character of Osteomyelitis

SIR,—May I endorse and enlarge on Mr. D. R. Richard's comments from Nigeria (19 August, p. 497) on "Changed Character of Osteomyelitis" (29 July, p. 255). I would like to stress particularly that, although the pattern in Europe and North America may have changed, both acute and chronic osteomyelitis must still be very common conditions in over three-quarters of the world's population. The complications caused by sickle-cell osteomyelitis and malnutrition add further to the problem. In Uganda osteomyelitis is common, and we have made the following observations:

(1) Although the metaphysis is the usual site for *non*-sickle-cell osteomyelitis to start, secondary involvement of the epiphysis of the lower and upper ends of the femur is common in small children. Patients often come for treatment late, and we have a number of cases with complete disappearance of the head of the femur and partial destruction of the lower end of the femur.

(2) In sickle-cell anaemia, also, the whole diaphysis[1] may be involved in the first few days. All four limbs may also be affected at the same time[2] and multiple fractures are common. *X*-ray changes as early as three days have been seen[3] and gross fragmentation of the bone at one week has been described.[4]

(3) Complete resolution and healing of pathological fractures as early as one month after early conservative treatment in young children is usual, but not inevitable. Patients may sometimes be very ill when pus is under tension, and the toxicity in itself may necessitate urgent early operation and decompression in an ill anaemic child.

(4) Blood culture is helpful in acute cases and stool culture for salmonellae may be useful. A needle down to the site of a suspected abscess most commonly provides a culture of *Staphylococcus pyogenes* or a salmonella (not *typhi*). This procedure has the advantage that crystalline penicillin (or other antibiotic) can replace any pus aspirated.

(5) In the vast majority of patients treated *within three days* conservative treatment appears to have been successful and operation unnecessary, provided that antibiotic therapy has been adequate. Late osteomyelitis is common, and massive sequestra will of course necessitate operative intervention.

(6) In the acute case in which operation is indicated the periosteum is incised rather than stripped. Drilling is usually *not* necessary for the friable bone in sickle-cell osteomyelitis. A fine polyethylene tube and six-hourly instillations of penicillin and streptomycin, plus the appropriate systemic antibiotic, has proved of value in these cases, as it has in chronic osteomyelitis.

(7) A tourniquet should never be used in patients with sickle-cell osteomyelitis, as gangrene may result.[5]—I am, etc.,

Ruptured Chordae Tendineae

SIR,—In reference to your leading article on ruptured chordae tendineae (12 August, p. 387) you state that "injection of contrast medium into the left ventricle . . . seldom shows the exact valvular lesion." While I would agree that it may be difficult to differentiate rupture of a papillary muscle from ruptured chorda, it is usually easy to distinguish the rigid valve of chronic rheumatic heart disease from the freely mobile flail valve seen when the subvalve apparatus parts company with the cusp. Two patients in whom ruptured chorda was correctly diagnosed preoperatively have been described.[1]

I would add that cineangiography as opposed to a slower filming technique is necessary to make this distinction.—I am, etc.,

Drugs and Driving

SIR,—Do your contributors realize how frightening it is for a layman to read (24 June, p. 836, and 8 July, p. 109) that doctors can hold the opinion that informing patients that they should not drive while taking the drugs they prescribe would tend to vitiate the "rapport existing between the doctor and patient"?

Expecting trust or rapport to be possible in the face of such callous indifference to the safety of patients and others seems utterly incomprehensible.

Equally dangerous is the habit of some doctors of not offering information on whether small or large amounts of alcohol can alter the effectiveness of any drug and its safety.—I am, etc.,

London S.W.1. JOHN ALLAN.

Recognition of Heart Failure

SIR,—Having read the article "Recognition of Heart Failure" (22 July, p. 219), may I raise one point which is, I think, of some clinical importance? It is stated in the above article that the venous pulse is impalpable in congestive cardiac failure. From our experience, a venous pulse associated with congestive cardiac failure and tricuspid incompetence is often palpable, almost to the same degree as the arterial pulse.—I am, etc.,

Nicosia, Cyprus. S. H. NICOLAIDES.

Stress Incontinence Treated by Electrical Stimulation

SIR,—I am delighted that one who has done as much excellent work in elucidating the problems of urinary incontinence as Mr. S. A. Vincent should also have observed the curative effect of pelvic floor muscle stimulation in cases of stress incontinence. It is interesting that, although not mentioned in the paper published with Mr. P. F. Schofield (15 July, p. 150), the chance observation I first made that pelvic floor contraction improved incontinence was in a case of neurogenic bladder, which Mr. Vincent (19 August, p. 498) states he has also experienced. Occasionally since my original observation I have met with cases of neurogenic urinary incontinence, often following spinal injury in which there has been a large degree of recovery, in which the incontinence due to residual weakness of the pelvic floor muscles has been more in the nature of a true stress incontinence. In these treatment by maximum perineal electrical stimulation has sometimes cured the incontinence.

Mr. Vincent also mentions cases of urge incontinence. Whether the treatment does any good to these cases or not depends upon the aetiology. Where the urge is due to inflammatory changes in the urethra (female prostatitis) the treatment is not likely to do any good, but the patients may be better because of the urethral dilatation associated with a cystoscopy also carried out at the same time. The treatment is of no value in urge incontinence due to neurogenic lesions or in the true congenital enuretic, who I believe suffers from a congenital type of uninhibited neurogenic bladder due to delayed development of the function of the ascending and descending tracts in the spinal cord. It is possible that some cases of urge incontinence are due to weakness of the pelvic floor allowing the urethra to shorten. One may regard these patients as just about to develop stress incontinence. If other causes of the symptoms are excluded and the urethra is shown to be less than normal length in the standing position it is quite possible that this treatment might cause great improvement. I know of one urological colleague who treats such patients by the Lapides operation and in a short series so far has not failed to cure one.

Maximum perineal electrical stimulation is, however, much easier to give and less trouble for both patient and surgeon.—I am, etc.,

THOMAS MOORE.

Department of Urology,
Manchester Royal Infirmary,
Manchester.

Trephine Biopsy of the Lung

SIR,—In reply to Dr. A. L. Jocobs's letter published in your columns (29 July, p. 310), we should like to add that a further 46 biopsies have been performed since the first 100 reported in our article (1 July, p. 30) without any instance of air embolism. Our experience in this respect is supported by the results of other workers, among them Dahlgren and Nordenström, who did not encounter air embolism in a series of 843 biopsies performed with a non-rotating needle.[1] Although air might conceivably enter the lung along the trephine during the changeover from drill to syringe, this is done very rapidly and the gloved thumb can be used to prevent ingress of air.—We are, etc.,

S. J. STEEL.
D. P. WINSTANLEY.

London Chest Hospital,
London E.2.

Healing Processes in Wounds

SIR,—In your leading article "Healing Processes in Wounds" (2 September, p. 571) you report "dramatic acceleration of healing of open wounds in patients given zinc sulphate 2 mg. three times daily by mouth."

In fact Pories *et al.*[1] were using 220 mg. of zinc sulphate three times daily in their trial with no reported ill effects.—I am, etc.,

L. A. RAUSCHER.

St. Pancras Hospital,
London N.W.1.

REFERENCE

[1] Pories, W. J., Henzel, J. H., Rob, C. G., and Strain, W. H., *Lancet*, 1967, 1, 121.

Mandrax and Porphyria

SIR,—Correspondence in your columns on the subject of Mandrax (methaqualone, diphenhydramine hydrochloride) (10 December 1966, p. 1455; 31 December 1966, p. 1655; 4 February, p. 301; 8 April, p. 112) prompts me to record my own experience with this drug in relation to its use in porphyric subjects.

I suffer from inherited familial porphyria (protocoproporphyria, "South African" porphyria) and am a member of the original family investigated by Dr. Geoffrey Dean.[1] Many drugs, and particularly barbiturates, are known to precipitate acute attacks of porphyria, and the choice of hypnotics in such cases is limited. I have myself taken Mandrax in a dosage of half a tablet at night as a hypnotic on several occasions and this has not precipitated an acute attack and it has not aggravated my skin symptoms. Full investigation may show that this drug can be used as a hypnotic in other types of porphyria.—I am, etc.,

C. M. VAN ROOYEN.

Transvaal,
South Africa.

Side-effect of Antidepressant Drugs

SIR,—Paresis of visual accommodation often deprives depressed patients being treated with dibenzepin derivatives—that is, imipramine and related compounds—of the therapeutic pleasures of reading and sewing, and is perhaps the most troublesome side-effect of these drugs.

Recently, with the help of Surgeon Commander Humphrey Hahn, my ophthalmic colleague, I have kept a small stock of plus-one lenses in N.H.S. frames and have lent them to patients with this symptom.

This simple remedy has quickly proved a most effective and much appreciated adjunct to treatment for depression.—I am, etc.,

G. G. WALLIS.

Royal Naval Hospital,
Bighi, Malta, G.C.

Reprints: Who Should Pay?

SIR,—During the past year a few short items written by myself have been published in medical journals. Since their publication I have received several requests for reprints from doctors in other countries.

Although I am very pleased to receive these requests and to send the reprint requested, the cost of both the reprinting and postage is considerable, and should in my opinion be borne by those who request the reprints, possibly by paying into a central pool.—I am, etc.,

Shepperton, D. MURRAY-BRUCE.
Middx.

Smallpox Revaccination

SIR,—Dr. Elizabeth L. M. Perkins (9 September, p. 680) has misquoted my letter to her partner Dr. Frank. My letter (22 June) is given in full below:

> "I was very disappointed to read in your letter dated 20 June 1967 that you propose to omit the revaccination of children after the eighth birthday.
>
> "This revaccination is to all intents and purposes devoid of risk, and, by denying this service to your young patients, I think that you run the risk of exposing them to a much more serious hazard when they are vaccinated later in life.
>
> "The schedules of vaccination and immunization have been recommended by the highest national authorities, promulgated by the Ministry of Health, and agreed locally by the health authority and the local medical committee. I hope very much that you will reconsider what appears to be your decision in this matter, and that you will agree to continue the arrangements for revaccinating the junior school children."

—I am, etc.,

T. McL. GALLOWAY,
County Medical Officer of Health, West Sussex.

Chichester,
Sussex.

B.M.A. as a Negotiating Body

SIR,—Your correspondent Dr. John Sinson (5 August, p. 374) is under a misapprehension about the talks at present going on between the British Medical Association and the Junior Hospital Doctors' Association. Your readers should know that the B.M.A., to which a proportion of hospital junior doctors belong, is *not* negotiating with the Minister of Health or any official person or body on behalf of the J.H.D.A. Neither have we asked that they should.

The fact that the B.M.A. is having talks with the J.H.D.A. about hospital junior doctors' representation has received wide publicity. The 4,200-strong J.H.D.A., conscious of its long-term responsibility of ensuring a united profession for future negotiations with the Review Body and the Ministry, invited the B.M.A. to follow the lead of other European medical associations by establishing an independent third stream of representation for hospital junior doctors within one employee organization, with its own constitution, including rules and fixed dates for elections.

Latterly the B.M.A.'s Representative Body at its A.R.M. has supported the continuation of these important talks.—I am, etc.,

J. H. BRIGGS,
Chairman,
Junior Hospital Doctors' Association.
London W.C.2.

Sales Promotion

SIR,—I wonder if I am alone in noticing a considerable increase in the number of representatives who now visit our practices and the frequency with which these gentlemen call ? In the past I have regarded the visits of representatives of the drug firms as a not unwelcome break in the surgery and as a useful means of keeping oneself familiar with the products of their companies. Now, however, these frequent visits are becoming an embarrassment and a nuisance.

Many years ago I gave up trying to cope with mail from the drug houses, and ever since then have consigned all mail from them unopened to the wastepaper basket. If this pestering by commercial gentlemen continues there will be only one method of dealing with it, and that is to refuse to see any representatives, and the drug companies will have severed yet another line of communication with at least one member of the medical profession.

Can nothing be done to impress upon these companies the folly of their present policy of persistent badgering of an already fully occupied profession ?—I am, etc.,

Newick, Sussex. J. R. CALDWELL.

Junior Staff Representation

SIR,—The Junior Hospital Doctors' Association in their newspaper *On Call*[1] have printed the following statement:

"Hospital junior doctors are *not* able to choose their representatives on the new Regional Hospital Services Committees—consultants only have the vote."

As this will have been read by many junior doctors, I think it important that it is prominently stated that junior doctors will, of course, have the duty to elect their own representatives to these committees. In this region seven seats on the hospital services committee have been allocated for junior doctors. Our problem at the moment is not lack of representation but consideration of how we can most efficiently and fairly elect the seven members.

It is obvious that the consultants on the regional committee would neither wish nor be competent to undertake these elections for us.—I am, etc.,

J. H. WETHERILL,
Honorary Chairman,
Leeds Region Hospital Junior Staffs Group, B.M.A.
Leeds.

Special Service for Doctors

SIR,—May I, through the courtesy of your correspondence columns, once again draw the attention of your readers to our special service for doctors which is to be held in All Souls Church, Langham Place, W.1, this year on Sunday, 8 October, at 11 a.m. ? We greatly value our link with the medical profession, and have been encouraged by the support which its members have given to these services during the last 15 years. Readers may be interested to know that this year the B.B.C. are recording the service for broadcast (in abbreviated form) on Sunday, 15 October, in the Home Service at 8 p.m. as well as in the World Service at 1715 hours and 0030 hours G.M.T. on 15 and 16 October respectively.

Lieutenant-General Sir Robert Drew, Director-General Army Medical Services, and Mr. D. F. Ellison Nash, consultant surgeon, St. Bartholomew's Hospital, and vice-president of the Christian Medical Fellowship, have kindly agreed to read the lessons.

A buffet lunch is again being arranged after the service at the Royal Society of Medicine, through the kind co-operation of the president and council of the society, at 15s. a head (adults) and 7s. 6d. a head (children aged 14 and under). A crèche will be open for children under 5 years in All Souls Church House during the service. We shall be happy to reserve seats in church for doctors and members of their families who apply for tickets in advance, and also to issue tickets for the lunch. Application (stating number of tickets required, and enclosing remittance for the luncheon) should be made to the Church Secretary, All Souls Vestry, 2 All Souls Place, London W.1, by Thursday, 5 October.

Special arrangements are available for doctors on call during the service, who may be contacted by telephone at All Souls Vestry, LAN. 3522.—I am, etc.,

JOHN R. W. STOTT,
Rector, All Souls Church.
London W.1.

Points from Letters

Mortality of the Ambulance Ride

Dr. E. M. HOARE (London N.W.3) writes: I have been interested to read the correspondence about the dangers of transporting very ill patients in ambulances (12 August, p. 438; 26 August, p. 560). . . . However, it is an aspect of the equipping of London ambulances which I wish to bring to your attention.

All ambulance crews are taught how to carry out external cardiac massage. Frequently gastric reflux occurs during this procedure—which is often provoked by the massage movements themselves. The patient is of necessity lying on his back, and in this position the risk of bronchial aspiration is considerable.

The crews are provided with no means of sucking out the mouth and pharynx if reflux occurs. Surely it would be a simple matter to install some sort of suction apparatus, perhaps of a type which operated off the vacuum of the vehicle's inlet manifold.

An even more obvious equipment lack is that of airways. Ambulances are not equipped with these despite their simplicity, cheapness, and efficiency in holding the tongue of the unconscious patient forward.

Twenty of the G.L.C. ambulances are equipped with tracheostomy tubes and a full set of surgical instruments (which are to be used only if a doctor is in attendance). Surely if this is justified the more elementary pieces of equipment suggested must be regarded as essential.

Casualty Department—or G.P. Service ?

Dr. A. J. BARSON (Toronto, Canada) writes: Casualty departments have most of the attributes of a good health centre. There is nursing and clerical help. Colleagues are always available for a second opinion and specialist services can easily be summoned. Pathological and radiological investigations essential to modern diagnostic work are readily obtained and the doctors who request them are more familiar with their interpretation than their older colleagues divorced from hospital medicine. Unfortunately, the hospital general-practitioner/casualty service falls short of the ideal in its lack of financial reward and consequent transience of its medical labour.

I was surprised that in Mr. B. J. Preston's survey (1 July, p. 46) no one said that they attended the casualty department because they received better treatment. Perhaps the public are a little more honest in the north of England where I did my casualty work. There the answer to the familiar question, "Why didn't you, see your own doctor about this ?" was all too often, "Oh, he would never examine me like they do here." When the general practitioner's surgery was open and across the road from the hospital I found the situation a little exasperating, but I could never bring myself to reprimand such a patient when he was obviously doing what his intelligence dictated.

Diet and Diverticulitis

Mr. HAROLD DODD (London W.1) writes: Referring to Mr. N. S. Painter's letter on diverticulitis (12 August, p. 434), may I say how much I agree with him ? In 1945, impressed by the contrast between the thin-walled normal colon, obviously designed to carry bulk, and the thickened small-lumened large bowel affected by diverticulitis, I advised not the conventional low residue diet but one leaving considerable bulk. Fresh and dried fruits, salads, vegetables, and a reasonable amount of protein supplanted the purées, minced, and sweet courses. An encouraging improvement followed. In a few a normal bowel action was regained, and in the majority the amount of aperient was reduced. . . . I am confident that the solution to the prevailing frequency of constipation, haemorrhoids, and diverticulitis lies in the return to natural unrefined foods, and that short-cuts in feeding with the abounding tinned and processed foods and sweets will not give the stable health that will stand the wear and tear of life without resort to medicines

Obituary Notices

J. A. HADFIELD, M.A., M.B., CH.B.

Dr. J. A. Hadfield, a former lecturer in psychopathology and mental hygiene at London University, and a well-known psychiatrist, died suddenly at his home at Whithurst Park, West Sussex, on 4 September. He was 84.

James Arthur Hadfield was born on 11 November 1882 in the Loyalty Isles, South Pacific, where his father, the Rev. James Hadfield, was a missionary. He was educated at Eltham College, Mansfield College, and Queen's College, Oxford, and at Edinburgh University. After graduation at Oxford Hadfield transferred to Edinburgh, where he graduated M.B., Ch.B. in 1916, and after house appointments at the Royal Infirmary he became a surgeon in the Royal Navy. Later he transferred to the R.A.M.C., and was neurologist at Ashhurst Neurological Hospital, Oxford. There his gifts as a teacher were quickly recognized by medical students. His next appointment was in 1920, as lecturer and university psychotherapist at Birmingham University. A year or two later he moved to London, and began his long career as a consultant in psychological medicine. Soon he joined the staff of the Tavistock Clinic, and also he lectured at Bethlem Royal Hospital on psychopathology. In 1931 he became lecturer in psychopathology and mental hygiene in London University, and held this appointment until 1958. At the university, and as director of studies at the Tavistock Clinic, Hadfield played a notable part in the training of medical men in psychiatry, to which he made many original contributions. In the 1930s he arranged lectures at the Tavistock Clinic for psychiatrists and general practitioners, and brought to London notable speakers from overseas, including C. G. Jung and William McDougall.

As a writer Hadfield's name became widely known through *Psychology and Morals* (1920), which ran into many editions. His colleagues pressed him to write more; but it was not until 1950 that *Psychology and Mental Health* appeared, followed four years later by *Dreams and Nightmares*. A further volume was to have been published this autumn.

Many doctors who later joined the staff of teaching hospitals went to Hadfield for a "training analysis," and for years a group of younger psychiatrists met regularly at his house for clinical discussions. Thus he exercised a wide influence on the development of dynamic psychotherapy.

Hadfield joined the R.A.M.C. in 1940, and attained the rank of lieutenant-colonel as officer in charge of a division at a war-time psychiatric hospital near Taunton. This hospital supplied many of the staff for the 41st Psychiatric Hospital in the Middle East. He was appointed a member of the Archbishop's Commission on Divine Healing in 1953.

Hadfield's wife qualified in medicine, as did two of his three sons. In his younger days Hadfield was keen on sailing and swimming, and at week-ends he kept open house for his friends at his country home in Sussex.—E. A. B.

B. T. SQUIRES, O.B.E., B.A., D.M.

Dr. B. T. Squires, a former director of medical services in Bechuanaland Protectorate, and a research worker at the National Institute of Medical Research in London, died suddenly in Bulawayo, Rhodesia, on 24 May, shortly after delivering a paper before the Scientific Conference on Nutrition, a subject very dear to him. He was 63.

Bernard Thomas Squires was born in Oxford on 12 June 1903, and began his academic life as a physiologist, taking a B.A. in animal physiology at University College, Oxford. His profound concern for mankind prompted him to enter the medical faculty at Guy's Hospital, and in 1929 he obtained the L.M.S.S.A. The following year he took the Conjoint diploma, and in 1931 he graduated B.M., B.Ch. The next five years were spent as a mission doctor working among the Bantu in South Africa, and during that time he submitted a thesis on medicine among the Basotho for which he was awarded the D.M. by Oxford University in 1936. In the same year Squires entered the medical service of Bechuanaland Protectorate, and while satisfying his missionary interests in caring for Bechuana he pursued his physiological researches into their state of nutrition, and developed techniques of study of tongue patterns and buccal smears. His contribution to the welfare of the Africans was recognized by the conferment of the O.B.E. in 1954, and by his appointment in 1956 as director of medical services.

When he retired in 1960 Dr. Squires continued his researches on nutrition, and he was the author of some forty papers on the subject. At the request of the National Institute for Medical Research in London he undertook in 1961 a nutritional survey in Basutoland for the Food and Agriculture Organization of the United Nations, and in 1964 he did a similar survey for the Aden Protectorate Government. In 1965 he returned to Africa, and continued working at Mpilo Hospital, Bulawayo. It is fitting that his last service to medicine and to mankind was a scientific paper on perhaps the world's greatest problem—nutrition.

It was a privilege to know and co-operate with Squires in Bechuanaland Protectorate, where he made such a magnificent contribution to the practice of medicine and to the understanding of our fellow men. His subtle humour and approachable manner endeared him to all—African and European alike. His colleagues held him in high esteem for his diagnostic ability and for his profound knowledge of basic medical principles. Above all, he was respected because he dealt justly, he loved mercy, and he walked humbly before his God. A missionary, a doctor, and a scientist has gone from our midst. To his widow, their three daughters, and a son—who is in practice as a barrister in Salisbury—we extend a deep and heartfelt sympathy.—J. M. S. M.

J. D. B. MACDOUGALL, M.D. F.R.C.S.ED.

Dr. J. D. B. MacDougall, senior lecturer in anatomy at the University of Dundee, died suddenly at his home in Dundee on 30 August. He was 49.

John David Bathgate MacDougall was born on 6 January 1918. Educated at Perth Academy and University College, Dundee, he graduated M.B., Ch.B. with commendation at the University of St. Andrews in 1942 and proceeded M.D. in 1946. Recurrent ill-health from the age of 17 years prevented him from joining the Services, though for a period he served as a civilian medical officer. Although he had a strong leaning to the practice of medicine, as is evident from his subsequent research interests, he decided to make anatomy his career, joining the staff of St. Salvator's College, St. Andrews, in 1943, and transferring to University College, Dundee, in 1946.

His interests in human anatomy and biology were wide; he had a long list of publications to his credit, and presented numerous communications to scientific societies. In the field of functional anatomy he made a particularly useful contribution in a special study of the masseter and temporalis muscles, correlating structure and function, and descriptions based on this work are now to be found in standard textbooks of anatomy.

Tissue culture was, however, his major research interest, and his early work in this field was concerned with the toxicity of materials in common clinical use, including various synthetic rubbers. The results obtained with silicone rubbers may have been partly responsible for its subsequent adoption in surgical practice and by the National Blood Transfusion Service. In 1956 he carried out research on tissue respiration at Columbia University, New York, and lectured at the Universities of Dalhousie, Toronto, and Western Ontario. In collaboration with the department of biochemistry he studied the effects of various sterols on the walls of arteries, and it is therefore particularly poignant that at the last he should be struck down by coronary heart disease.

Perhaps the most interesting developments in his research work since 1961 have been concerned with his initiation of the culture of adult organs under hyperbaric oxygen. In collaboration with a friend and colleague, this was subsequently extended to a wider study on the toxic effects of hyperbaric oxygen on cell structure and function. This work has revealed many hitherto unpublished changes in cell structure, and is currently being prepared for publication.

He was a most loyal and conscientious member of staff, and one who was both liked and respected by colleagues and students. Generations of medical and dental undergraduates will recall with gratitude his lucid lectures, interspersed as they were with the fruits of wide reading and a philosophic outlook, while junior staff preparing for the primary F.R.C.S. can have had no better guide. He was the kindliest of men, thoughtful, possessed of great integrity of character and an innate modesty. Students and staff alike will miss a genial member of the academic society, and our deepest sympathy goes to his widow, his young daughter, and his son, who is a medical student at St. Andrews.—D. R. D. and R. E. C.

J. B. DAVEY, M.B., D.T.M.

Dr. J. B. Davey, former principal medical officer and member of the executive council of Tanganyika Territory, died in Worthing on 29 June. He was 92.

John Bernard Davey, son of the Rev. John Davey, was born in Coatham, Yorkshire, on 31 March 1875, and was educated at Giggleswick School, Yorkshire, the Middlesex Hospital, and University College, London, qualifying with the Conjoint diploma in 1899 and graduating M.B. the following year. After early house appointments at the Middlesex Hospital he took part in the Boer War as civil surgeon to the South African Field Forces, and was awarded the South African War medal and clasp, before being appointed medical officer in the Nyasaland Protectorate from 1902 to 1919. During a period of leave he took the D.T.M. in 1907. He was seconded for a period of service with the scientific commission of the Royal Society, headed by Colonel Sir David Bruce, which went to Nyasaland in 1911 to investigate the relation of the African fauna to the existence and spread of the trypanosome diseases of man and domestic animals. In 1919 he was appointed principal medical officer in occupied German East Africa, later Tanganyika Territory, and the following year he became a member of the executive council. In 1923–4 he was president of the Tanganyika Branch of the British Medical Association, and in 1924 was a representative at the Annual Meeting. On his retirement from Tanganyika in 1924 he returned to London, and undertook a year's pathology at the Middlesex Hospital, after which he spent some eight years as a clinical pathologist in the Cheltenham area before retiring for a second time.

During the second world war, when there was an acute shortage of medical staff, he emerged from his second retirement and returned to Tanganyika for two years as provincial medical officer.

A colleague writes: When in 1902 Dr. Davey joined the Colonial Service in British Central Africa (Nyasaland) it is recorded that his was the only microscope there. After distinguished medical service in Africa he retired in 1924. Following a year's study of pathology at the Middlesex Hospital he was appointed clinical pathologist at Cheltenham, but was forced by double cataract to abandon microscopy in 1933. Never giving up medical work, during the second world war he again offered his services to the Colonial Office, and served for two years as a provincial medical officer in Tanganyika in the department of which he had been the first director. From 1948 he lived in South Africa, finally moving to Worthing in 1963. He married in 1913; and to his widow, Constance, who shared with him the hardships of those early days in Africa, and their two daughters we extend our sincere sympathy and mourn the passing of a distinguished colleague.

G. McL. writes: All of us who knew Dr. J. B. Davey in Tanganyika would agree that he made a success of an exceptionally difficult task when he directed the health services of that vast territory. It was then still suffering from the aftermath of war and the wartime influenza epidemic, and with its numerous parasitic diseases almost uncontrolled. There were, besides, several outbreaks of smallpox. In 1921 there was a new outbreak of plague, and in 1922 Rhodesian sleeping sickness, which had been smouldering for some time, was now appearing in epidemic form. With little more than a skeleton staff to begin with, and with barely enough funds to equip them properly, it was a disheartening situation. Dr. Davey persevered, however, building up a department with such slender means as he had at his disposal. When he left in 1924 the foundations were prepared for the extension of the medical services. Despite his many other duties, Dr. Davey was able to take a special interest in the sleeping sickness epidemic, and took an active part in the controversy—then renewed—of whether wild game acted as a reservoir of infection. He sided with those who incriminated game, but it was only after he had retired that it was shown experimentally that trypanosomes could infect man after passage through certain game animals.

Dr. Davey was a hard-working and conscientious public servant, and he upheld the best traditions of his profession.

K. A. W. LAW, M.B.E., M.B., B.S.

Dr. K. A. W. Law, a medical practitioner in Newcastle upon Tyne, died suddenly on 5 August after a short illness. He was 65.

Kenneth Arthur Waring Law, son of the Reverend W. L. M. Law of Hetton-le-Hole, Co. Durham, was born on 4 October 1901, and was educated at Durham School and University, graduating M.B., B.S. in 1926. He played Rugby for the school and university. After an appointment as house surgeon at the Royal Victoria Infirmary he was appointed a medical officer to the Blue Funnel Line in 1926–7, on the United Kingdom and Japan route. He was one of the founder members, with Professor Farquar Murray, of the Blue Funnel Club (medical) which meets annually in Newcastle, and was a most efficient secretary over the past 15 years. In 1927 he married, and after a short time in practice at Leigh-on-Sea he returned to Tyneside in 1932 to take a practice in Forest Hall, Newcastle upon Tyne, where he worked until his death. In 1938 he joined the Royal Auxiliary Air Force, and was called up for service with the Royal Air Force Medical Branch at the outbreak of the second world war. In 1944 the M.B.E. was conferred on him. Dr. Law was a keen committee man, and among his many activities he was chairman in 1951–2 of the Newcastle Division of the British Medical Association. He also served on the Branch council, and was a representative at the Annual Meeting in 1950 and 1952.

Kenneth was a real family practitioner, always willing to help his patients. He was a good sportsman, and in the later years enjoyed his "Tuesday foursome" at golf. Above all he was a great family man, dedicated to his wife and two daughters, and his four grandchildren. He was critical, but always helpful, to his junior colleagues, and I have never heard him speak badly of anyone. His family, his colleagues, and his friends have lost a good friend.—J. H. P.

G. JAMIESON, M.B., CH.B.

Dr. G. Jamieson, formerly in general practice at Chryston, in North Lanarkshire, died at his home on 25 August aged 70.

George Jamieson was born on 4 October 1896, and after serving his apprenticeship in the Royal Bank of Scotland, Airdrie, he decided that medicine was his vocation. He entered the University of Glasgow, but his studies were interrupted by the first world war, in which he served as surgeon sub-lieutenant in the R.N.V.R. After demobilization he completed his studies, graduating M.B., B.S. in 1920. He immediately entered general practice. Dr. Jamieson was chairman of the Lanarkshire Division of the B.M.A. in 1940–1, and was a member of the N.H.S. executive council for the County of Lanarkshire. He was a founder member of the College of General Practitioners, and served on the board of management of the north-eastern group of mental hospitals. He was past-president of the local nursing association and also past-chairman of the committee of management of the Lanarkshire Association of District Nurses. Other appointments he held were factory doctor and Treasury medical officer. In 1938 he was appointed a justice of the peace for the County of Lanarkshire, and thereafter served on various licensing boards.

Dr. Jamieson was the born general practitioner. He was tremendously interested in people, and looked on his patients as friends, being interested not only in their illnesses but in their everyday lives. He was always willing to help in any capacity, and was the "doctors' doctor," keeping himself continually up to date, always seeking postgraduate experience. He had boundless energy, and participated in all the activities which took place around the area of his practice. He was shrewd and disarming, and had he not been so devoted to his work there is no doubt that he would have been very successful in business.

He is survived by his wife, two daughters, and two sons. Both daughters and one of his sons are in the medical profession. The sympathy of all his friends and colleagues is extended to his widow and family.—J. J.

D. SKINNER, M.B., CH.B.

Dr. D. Skinner, a general practitioner in Burnley, died on 22 August, only three weeks after his retirement. He was 66.

David Skinner was born on 8 October 1900 in India, where his father was principal of the Madras Christian College. He was brought to Scotland as a child, and was educated first at St. Andrews and later at Aberdeen Grammar School and Aberdeen University, graduating M.B., Ch.B. in 1924. After house appointments in hospitals in Aberdeenshire he joined a partnership in a large general practice in Burnley in 1925, where his outstanding qualities as a doctor were soon recognized. As well as being a fine clinician he was a very skilled anaesthetist, and for over 30 years held appointments as an anaesthetist to the Burnley group of hospitals. As a member of the Volunteer Reserve of the Royal Air Force he was called up at the outbreak of the second world war, serving mostly in the Mediterranean area with the 8th Army, reaching the rank of wing commander and being mentioned in dispatches for his services. Invalided out of the R.A.F. in 1945, following a coronary thrombosis, he returned to general practice in Burnley.

A member of the panel committee in the N.H.I. days, he was a member of the local medical committee from 1948 to 1951, from 1951 to 1960 he was honorary secretary, and was chairman from 1960 to 1965. He was also a member of the Burnley Executive Council from 1952 to 1965, and for many years served on the hospitals medical advisory committee. A member of the Burnley Division of the British Medical Association, he was a representative at the Annual Meeting in 1952, and served as chairman of the Division for the year 1952–3. At the time of his death he was a member of the ethical committee of the Division.

David Skinner's great love, apart from the practice of medicine, was fishing, at which he excelled, and all his holidays were spent in pursuit of this hobby. Enjoying an ideal family life, his quiet competent manner, his dry sense of humour, his ability and integrity endeared him to his patients and friends, and our sympathy is extended to his widow, son, and daughter.—R. S. McG.

J. M. DAVIDSON, M.B., CH.B.

Dr. J. M. Davidson, formerly in general practice at Docking, Norfolk, died suddenly at his home in Kendal on 26 August. He was 64.

John Macrae Davidson, son of an Edinburgh practitioner, was born on 21 March 1903, and was educated at Loretto School and Edinburgh University, graduating M.B., Ch.B. in 1929. As an undergraduate he took an active part in the corporate life of the university, serving on the committee of the Union, and playing hockey for the university. After an appointment as house-surgeon at Chalmers Hospital, Edinburgh, he went into general practice in the Midlands for a short time before settling down in a rural practice at Docking, in Norfolk, where he remained until his retirement four years ago. Always interested in community life, he devoted much of his leisure to parish and church work, and for a time he was chairman of the parish council. In this community work he was ably supported by his wife, and many were the gestures of appreciation on his retirement. Even in retirement the habits of a lifetime were not broken, and he entered into community work in Kendal with his accustomed vigour, continuing to lead a full life for the benefit of others.

He is survived by his widow and three children, who in their hour of sorrow must be proud to remember his sense of duty and life of service.—G. G.

JANET WHYTE HEPBURN, M.B. CH.B., D.P.H.

Dr. J. W. Hepburn, a former senior assistant medical officer of health for maternity and child welfare, Grimsby County Borough, died on 9 August 1967. She was 72.

Janet Whyte Hepburn graduated M.B., B.S. from Glasgow University in 1918, and later studied at Cambridge for the diploma in Public Health. She worked in a Glasgow children's hospital and later moved to the West Norfolk Hospital. Her duties with the Grimsby Health Department began in 1922, and at once she exerted great influence on the development of Grimsby's maternal and child welfare clinics.

Grimsby then had three clinics. They were always crowded and often had between 80 and 100 mothers packed into the waiting-room at each of them. When she retired in September 1960, after 38 years' service, Dr. Hepburn was able to say that real want had gone, family allowances helped mothers in need, and those who attended clinics did so mainly for advice.

She always inspired great trust, and had an unbeatable record of service. She will be remembered chiefly for her excellent mother-and-child work.—R. G.

B. E. A. HARLEY, M.R.C.S., L.R.C.P. D.O.

Dr. B. E. A. Harley, honorary ophthalmic surgeon at the Wangaratta District Base Hospital, died suddenly at his home at Wangaratta, in Victoria, Australia, on 21 November 1966. He was 57.

Brian Erskine Alfred Harley, son of Dr. H. Harley, a general practitioner in Wealdstone, Middlesex, was born in Harrow on 1 July, 1909, and educated at Felstead, Essex, and at the Middlesex Hospital, qualifying with the Conjoint diploma in 1933. Within a month of his qualification his father died, and he returned home to take over the practice. He later moved to Lorley, Yorkshire, where he practised until the outbreak of the second world war, when he volunteered for service with the Royal Air Force. During his service he was stationed in England, Scotland, and Wales. While in Scotland he organized the Mountain Rescue Service, developing much of the equipment which is still in use to this day. After demobilization he returned to general practice in Lorley until 1948, when he moved to Didbrook, Gloucestershire, where he bought a mixed farm. He took the diploma in ophthalmology in 1954, and in the same year moved with his family to Australia, where he bought the Wangaratta portion of Dr. Rosen's ophthalmic practice. He became honorary ophthalmic surgeon at the Wangaratta District Base Hospital, and also consulted in Benalla. The Victorian police sought his assistance in forming a search and rescue squad, and some of the equipment was patterned on his mountain rescue equipment.

Brian took part in many activities in Wangaratta, and was a Rotarian and a member of the regional library committee. His friends will always remember him, his warmth, gaiety, and gentleness; and he was loved by his patients. To Isabel and their two daughters we extend our deepest sympathy. —D. M. W.

TERENCE EAST, M.A., D.M., F.R.C.P.

D. S. M. writes: I remember very clearly the first time I saw Terence East (obituary, 9 September, p. 684). He gave the introductory lecture to the course in medicine at King's. As he entered the lecture theatre I was aware immediately of the presence of a great man. His walk was distinctive: he inclined his head very slightly to one side and appeared to look into the far distance. He was tall and strongly built, with bronzed skin and iron-grey hair. He spoke with a deep voice that was melodious and difficult to hear until you got used to it. He explained simply and clearly, writing little on the blackboard. His ward rounds and clinics were fascinating. The round began with his reading the student notes carefully and making helpful comments on them. Then he would demonstrate the physical signs, waiting patiently until each student was confident of them. Afterwards he would explain the pathology by use of the museum specimens, many of which he had prepared himself. His clinics were conducted in the same way. What remains, above all, is his voice in my mind's ear as he taught and described. He would make a point by quotations from ancient and modern literature, and by observation of current events. His interests were varied. His mind ranged widely, and always constructively. "Only connect . . ." —and he could.

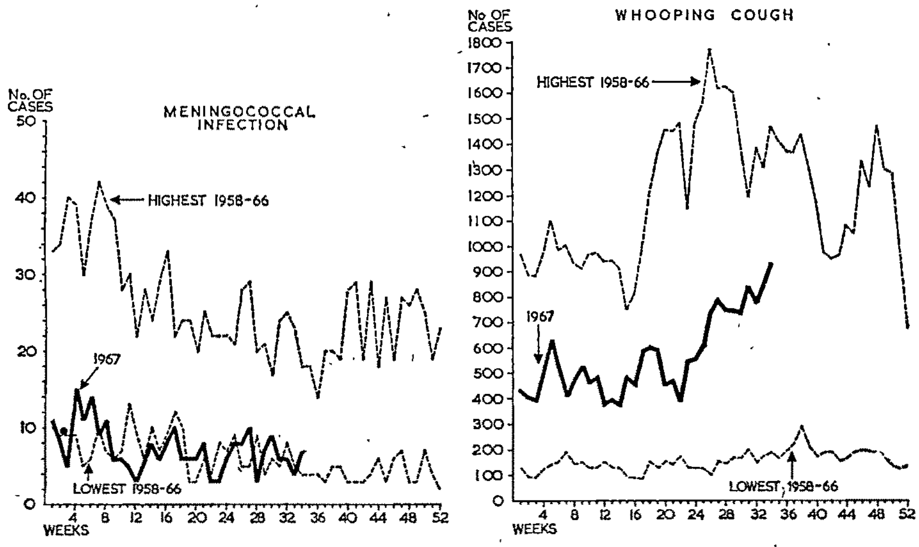
It is a tragedy that many misunderstood him, and because they could not hear (he did not like to repeat, conscious of his difficult enunciation) took no trouble and missed so much. The last time I met him, a few months before he died, we sat on a bench in his garden in Cornwall. He talked, as ever, with great interest. He had new plans and ideas. He could still illuminate. He was one of the great men I have been privileged to know and to learn from.

News and Notes

EPIDEMIOLOGY

Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of meningococcal infection and whooping-cough in England and Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.



Scotland in First Quarter

The birth rate for the first quarter of 1967 was 19.7 per 1,000 population. This was 0.9 above the rate for the first quarter of 1966 and 0.3 below the average of the five preceding first quarters. The infant mortality rate was 21 and the neonatal mortality rate was 13 per 1,000 live births. These were 4 and 3 respectively below the rates for the first quarter of 1966. Stillbirths formed 15 per 1,000 total births, giving a rate of 4 below the average. The general death rate was 12.4 per 1,000 population and was 2.8 below the rate for the corresponding quarter of 1966 and 2.1 below the average.

Sixty-two deaths were registered from respiratory tuberculosis and 6 from other forms of tuberculosis; these were 33 and 10 respectively fewer than in the first quarter of 1966. Deaths attributed to cancer of the respiratory system were 757 and were 32 fewer than in the corresponding quarter of 1966. Deaths due to motor-vehicle accidents numbered 172 and were 20 more than in the

INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **26 August** (No. 34) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included) Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

Soul and Conscience Reports

The Chairman of the B.M.A. Scottish Council, Dr. J. Riddell, has written to all doctors in Scotland commenting on " soul and conscience " reports. The letter refers to cases in which a family doctor has felt unable to sign a death certificate, either because he has not seen the patient in the weeks immediately preceding death or because of some other kind of uncertainty. It has been reported, says Dr. Riddell, that in such cases the procurator-fiscal asks a second doctor who had not previously seen the patient to give a " soul and conscience " report as to the cause of death. On receipt of the report permission to bury the body is given by the procurator-fiscal.

The Crown Office has stated that such action on the part of procurators-fiscal is in accordance with instructions laid down by the Lord Advocate. These instructions make it clear that the fact that the cause of death is, in the medical sense, unexplained is not a ground for ordering a post-mortem examination at the public expense if the extrinsic circumstances sufficiently explain the cause of death and do not raise a suspicion of criminality or negligence. Therefore, so long as there is no suspicion of criminality or negligence, the procurator-fiscal is not concerned with ascertaining the actual cause of death where this is not apparent from an external examination of the body. Nor is he interested in cases which might give rise to civil actions.

The Scottish Council has told the Crown Office that doctors are more likely to feel that in cases of doubt crime cannot be excluded until the cause of death has been definitely ascertained, usually by post-mortem examination. It was suggested by the Crown Office, however, that as the procurator-fiscal cannot go beyond the instructions of the Lord Advocate it is for the B.M.A. to advise its members that a death certificate, or a soul and conscience report, should not be issued by a doctor if he is in any doubt that death was not from natural causes.

The view of the Scottish Council is that a death certificate, or a soul and conscience report, should be given only when the certifying doctor is absolutely sure that criminal activity was not the direct or a contributory cause of death.

MEDICAL NEWS

Sergeant-Surgeon to the Queen

Sir RALPH MARNHAM, surgeon to the Queen since 1953 and before then surgeon to George VI, has been appointed sergeant-surgeon to the Queen. He succeeds Sir ARTHUR PORRITT, who has resigned. Sir Ralph, who is surgeon to St. George's Hospital, London, was educated at Gonville and Caius College, Cambridge, and at St. George's. He was president of the Association of Surgeons of Great Britain and Ireland in 1965.

£500,000 Gift for Cancer Research

Mr. MICHAEL SOBELL, of Bakeham House, Englefield Green, Surrey, has given £500,000 for the purpose of acquiring premises in London that will serve as a permanent head-quarters for the College of Pathologists and the British Empire Cancer Campaign for Research. The object is to facilitate and strengthen collaboration between these two bodies.

Fellowships in Medicine

The following appointments have been made by the Medical Research Council to Fellowships in Medicine for the academic year 1967–8.

Medical Research Council Travelling Fellowships : Dr. D. C. FLENLEY, Dr. A. V. HOFFBRAND, Dr. D. OGSTON, Dr. B. E. B. MOSELEY, Dr. J. A. SONNABEND, and Dr. P. C. WILKINSON. *Sir Henry Wellcome Travelling Fellowships :* Dr. M. FRIEDMAN, Dr. T. A. MCNEILL, Dr. D. P. ROSE, Dr. J. STEINER, and Mr. J. W. TURNER. *Clinical Research Fellowships :* Dr. S. P. ALLISON, Dr. J. A. BIRTCHNELL, Dr. T. J. PETERS, Dr. G. M. STERLING, and Dr. R. P. H. THOMPSON. *Dorothy Temple Cross Research Fellowship :* Dr. I. D. GREEN. *Alexander Pigott Wernher Memorial Trust Fellowships in Ophthalmology and Otology :* Mr. M. D. SANDERS and Dr. B. SHUKLA. *United States Public Health Service Fellowships :* Dr. J. BRADLEY, Dr. D. R. FERGUSON, Dr. H. FOX, Dr. J. A. MCBRIDE, Dr. R. O. WELLER, and Dr. M. R. WILLS. *Lilly International Fellowship :* Dr. F. J. GOODWIN.

Drug Industry Report

According to a leaflet issued by the Association of the British Pharmaceutical Industry only 2d. per person per day is spent on N.H.S. medicines, compared with 17d. on smoking and alcohol. In hospitals pharmaceutical supplies are said to account for only 2.4% of the total expenditure. The association points out that the number of patients in mental hospitals has fallen by 25,000 since the mid-1950s, when the tranquillizers and antidepressives were first marketed. It also notes that the introduction of the sulphonamides, penicillin, and other antibiotics has reduced the number of deaths from puerperal sepsis from 657 in 1935 to 5 in 1965. The industry in Britain spends about £12m. a year on research. In 1966 its return on capital averaged 20% to 25%, "a figure which is in line with that achieved by the successful and efficient sector of British industry."

Hospital Pharmacy Staffing

The London branch of the Guild of Public Pharmacists has found in its area an overall shortage of hospital pharmacists (35%). According to a survey less than half the established posts have been filled by the same pharmacist for more than two years. Of the pharmacists who resigned their posts during the 12 months preceding the survey less than a third took up other hospital appointments. About half the reported vacancies for the senior grades have remained unfilled for over two years. In the basic grade the deficiency of full-time pharmacists exceeded 80%. Besides indicating a serious shortage of staff in the area, the survey has suggested that the service is not considered by the possible young entrant to offer a worth-while career.

Royal Medical Benevolent Fund

At the annual general meeting, held on 5 September, the following officials were re-elected: *president,* Sir ZACHARY COPE ; *honorary secretary,* Dr. T. ANWYL-DAVIES ; *honorary treasurer,* Mr. G. H. BATEMAN. During 1966 a total of £55,482 was distributed in grants and annuities.

Royal Society of Tropical Medicine and Hygiene

Professor A. CORRADETTI, director of the department of parasitology and entomology, Istituo Superiore di Sanità, Rome, and Dr. CLAY G. HUFF, chief parasitologist at the Naval Research Institute in Washington, have been elected Honorary Fellows of the Royal Society of Tropical Medicine and Hygiene.

Designing for the Disabled

Special facilities for the disabled should be provided in public buildings. This is advocated in an article in the September issue of the *Journal of the Royal Institute of British Architects*. The writer, Mr. Selwyn Goldsmith, an architect and himself partly disabled, is the author of *Designing for the Disabled* (see *B.M.J.*, 1964, 18 January, p. 172). In planning buildings, he says, architects should think in terms of a normal population and of a parallel and distinct abnormal population as well. There is a moral obligation on the architect and his client to provide suitable arrangements for the physically handicapped. Usable lavatory facilities, he points out, are commonly of much greater concern to disabled people than the presence or absence of steps at the entrances to buildings.

Extension of Benefit

A scheme amending the Pneumoconiosis, Byssinosis and Miscellaneous Diseases Benefit Scheme, 1966, adds three diseases to those in respect of which benefit is payable. They are carcinoma of the mucous membrane of the nose or associated sinuses and primary carcinoma of a bronchus or of a lung; papilloma of the bladder; and diffuse mesothelioma. The scheme came into operation on 31 August.

T.U.C. Conference

Delegates at the T.U.C. conference last week approved a motion urging the Government to take steps to safeguard the health of all workers using asbestos, and to introduce licensing and inspection arrangements. A resolution was also carried calling for the institution of an occupational health service.

World Medical Association

The address of Mr. H. W. Paines, honorary secretary of the British Supporting Group of the World Medical Association, is now 1 Sandy Lodge Way, Northwood, Middlesex.

Medical Guide for Ships

A medical guide for ships has been designed for use by all countries. It consists of a medical guide proper, a ship's medicine chest, and a medical code of signals. Each section is co-ordinated with the others, so that the task of the ship's master and of the doctor radioing advice is made as simple as possible. The guide has been sponsored by the International Labour Office, the International Maritime Consultative Organization, and the World Health Organization and is the first attempt to overcome the limitations of national guides. (H.M.S.O., £2.)

Animal Welfare

A Farm Animal Welfare Committee has been set up by the Minister of Agriculture and the Secretary of State for Scotland to advise on matters relating to the welfare of animals kept under intensive husbandry systems. The chairman is Professor H. R. Hewer, professor of zoology at Imperial College. Other members include Dr. M. H. Draper, of the physiology department, Edinburgh University; Dr. J. A. B. Gray, second secretary, Medical Research Council; and Major W. N. Scott, scientific secretary, Universities Federation for Animal Welfare.

People in the News

▶ Sir Harry Crane has been appointed chairman of the Industrial Injuries Advisory Council in succession to Professor Sir Arnold Plant.

▶ Dr. R. I. S. Bayliss has been appointed the McLaughlin Gallie Travelling Professor of the Royal College of Physicians and Surgeons of Canada. He will be visiting Canada from 8 October to 4 November.

News in Brief

The Luton and Dunstable Hospital medical centre, which was opened in April (see *B.M.J.*, 8 July, p. 120), plans to issue a journal three times a year. Its first number tells the story of the centre. Regular features will include postgraduate news, B.M.A. notes, and reviews and annotations.

Recent Publications

Your Home and Your Rheumatism, an illustrated booklet, is intended to help people who are disabled to overcome difficulties in their everyday living. The aids referred to in the text are listed at the end with addresses of suppliers. Copies of the booklet can be obtained from the Arthritis and Rheumatism Council, 10 Charing Cross Road, London W.C.2, price 2s., including postage.

Reports of a series of conference and discussion sessions held last year at the Scottish Hospital Centre are available in a single publication (*Collected Conference Reports, 1966*, Scottish Hospital Centre, Crewe Road South, Edinburgh 4, 10s.).

Selected Annotated Bibliography: Home Care Services of the Chronically Ill and Aged, revised 1967, prepared by the Institute of Gerontology, University of Iowa, Iowa City, Iowa, U.S.A.

Coming Events

Royal College of General Practitioners (South Ireland Faculty).—Annual postgraduate course, 2–6 October, University College, Cork. Details from Dr. John Gowen, Strand House, Youghal, County Cork.

King Edward's Hospital Fund for London.—Showing of filmstrips on voluntary services in hospitals, 4 October, Hospital Centre. Fee 6s. or 10s., including buffet lunch. Exhibition on display, "The Patient within the Community."

British Association of Manipulative Medicine.—Lecture by Dr. A. W. Spence on "Obesity," Thursday, 5 October, 8 p.m., in London. Details from honorary secretary, 3 Arundel Terrace, Brighton 7, Sussex.

Institute of Diseases of the Chest.—Free clinical demonstrations for medical practitioners, Fridays, 5 p.m., 6 October to 8 December, Institute's lecture theatre (in grounds of Brompton Hospital), Fulham Road, London S.W.3.

Carworth Europe.—Second annual symposium, "The Interaction of the Laboratory Animal with its Microflora," 6 October, Large Lecture Theatre, Physiological Laboratory, Downing Street, Cambridge. Details from Carworth Europe, Alconbury, Huntingdon.

British Medical Association (Edinburgh and South-east Scotland Branch).—Conference, "Better Medical Care—Which Road?" 7 October, David Hume Tower, Edinburgh University. Applications, enclosing 5s. registration fee, to B.M.A. Scottish House, 7 Drumsheugh Gardens, Edinburgh 3. It is hoped there will be a large attendance of B.M.A. members and others interested.

British Diabetic Association.—Symposium for general practitioners, 8 October, 11 a.m., King's College Hospital (School of Nursing Lecture Theatre), London S.E.5. Details from Dr. D. M. Hill, Royal Sussex County Hospital, Brighton 7.

Royal Free Hospital School of Medicine.—Inaugural address by Professor Sir John McMichael, F.R.S., 11 October, 3 p.m., Senate House, London W.C.1.

The Industrial Society.—Conference on industrial health, 12 October, Café Royal, London W.1. Details from Mr. Angus Stewart, Robert Hyde House, 48 Bryanston Square, London W.1.

Fever Hospital Medical Services Group and Association of Infectious Diseases Physicians.—Joint meeting, 13–14 October, St. Ann's General Hospital, Tottenham, London N.15. Details from Dr. S. R. Jamieson, Castle Hill Hospital, Castle Road, Cottingham, Yorkshire.

Institute of Urology.—Week-end Course on "Urology for Higher Examinations," 20–22 October. For details see advertisement on p. xxxvii.

Biochemical Society.—Meeting, 20–21 October, National Institute for Medical Research, Mill Hill, London N.W.7. Programme will include colloquium on "Functions of Nucleic Acids in the Cytoplasm." Details from Executive Secretary, Biochemical Society, 7 Warwick Court, London W.C.1.

British Council.—Course in anaesthesia in collaboration with the faculty of anaesthetists of the Royal College of Surgeons of England, 4–17 February 1968. Applications by 31 October. Details from Director, Courses Department, British Council, 97/99 Park Street, London W.1.

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 18 September

Chelmsford Medical Education and Research Trust.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.

Kingston-upon-Thames Medical Centre.—5.15 p.m., Dr. M. E. A. Powell: Slide Seminar—Kidney.●

Medical Research Council.—At National Institute for Medical Research Laboratories, Hampstead, London N.W., 4.30 p.m., Dr. D. H. Lewis: Family at Sea—a Study of Crowded Isolation.

Tuesday, 19 September

B.B.C. 1 Television.—11.20 p.m. (approximately) medicine today: Fits. (Sponsored by A.S.M.E.)

Institute of Obstetrics and Gynaecology.—At Hammersmith Hospital, (1) 2 p.m., Mr. D. J. Neal Smith: Scope and Value of Cervical Cytology Clinics; (2) 4.30 p.m., Professor V. Dobrovici (Rumania): Obstetrical Attendance in Rumania—a New Interpretation of the Trial Labour. (Admission by ticket only, obtainable from Secretary, Institute of Obstetrics and Gynaecology, Chelsea Hospital for Women, London S.W.)●

Leukaemia Research Fund.—At Institute of Child Health, London W.C., 5.30 p.m., Professor H. S. Kaplan (Stanford University, U.S.A.): On the Natural History of the Murine Leukaemias.●

WHIPPS CROSS HOSPITAL MEDICAL EDUCATION CENTRE.—1 p.m., clinical meeting.

Wednesday, 20 September

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.

STOKE MANDEVILLE HOSPITAL.—6 p.m., Dr. D. C. Watt: Psychiatric Examinations and Diagnosis.

Friday, 22 September

KINGSTON-UPON-THAMES MEDICAL CENTRE.—2.30 p.m., Dr. A. A. Cunningham: Neonatal Resuscitation.

NORTHAMPTON MEDICAL SOCIETY.—8 for 8.30 p.m., presidential address by Dr. D. G. H. MacQuaide.

SUSSEX POSTGRADUATE MEDICAL CENTRE. — At Brighton General Hospital, 8.30 p.m., Professor G. M. Carstairs: Over-population and Behaviour Pathology—Observations in Animals and Man.

Appointments

ARMY.—E. G. Muir, M.B., M.S., F.R.C.S. (honorary consultant in surgery to the Army).

NATIONAL HOSPITALS FOR NERVOUS DISEASES.—H. Ludman, M.B., F.R.C.S. (consultant surgeon in neuro-otology at the National Hospital, Queen Square, London W C.).

NORTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—R. H. Robinson, M.B., F.F.A. R.C.S. (consultant anaesthetist to Harlow Group of Hospitals).

SOUTH-EAST METROPOLITAN REGIONAL HOSPITAL BOARD.—Dorothy J. Whitney, M.B., F.R.C.S., M.R.C.O.G. (consultant in obstetrics and gynaecology, Mid-Sussex group) ; E. B. Lewis, M.B., B.Chir., F.F.A. R.C.S. (consultant in anaesthetics, South-east Kent group) ; J. L. Dawson, M.B., M.S., F.R.C.S. (consultant in general surgery, Bromley group) ; B. A. Latham, M.B., M.R.C.P., M.R.A.C.P., D.Phys.Med. (consultant in physical medicine, Brighton and Lewes group) ; A. K. McKinlay, B.M., F.F.R., D.M.R.D. (consultant in radiology, Woolwich group) ; T. A. Casey, M.B., M.Ch., F.R.C.S., D.O. (consultant in ophthalmology, Tunbridge Wells, Central Kent, and Brighton and Lewes groups) ; P. J. Jennings, M.B., F.R.C.S. (consultant in general surgery, Medway and Gravesend group) ; J. Rhodes, M.B., F.F.R., D.M.R.D. (consultant in radiology, Eastbourne and Hailsham groups) ; J. T. Snow, M.B., F.R.C.S., D.O. (consultant in ophthalmology, South-east Kent and Canterbury groups).

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

JOURNAL OF NEUROLOGY, NEUROSURGERY AND PSYCHIATRY

Contents of the August issue are as follows :

Effects of Neonatal Hypoglycaemia on the Nervous System : a Pathological Study. John M. Anderson, R. D. G. Milner, and Sabina J. Strich.

Peripheral Neuropathy of Metachromatic Leucodystrophy : Observations on Segmental Demyelination and Remyelination and the Intracellular Distribution of Sulphatide. A. D. Dayan.

Independence of the Galvanic Skin Reflex from the Vasoconstrictor Reflex in Man. B. J. Prout.

Excitability of Spinal Motor Neurones in Normal Subjects and Patients with Spasticity, Parkinsonian Rigidity, and Cerebellar Hypotonia. P. Zander Olsen and E. Diamantopoulos.

An Improved Technique for Radial Nerve Conduction Studies. Allan W. Downie and Thomas R. Scott.

Laterality Differences in the Perception of Pressure. Eileen Fennell, Paul Satz, and Robert Wise.

Granulomatous Meningitis and Diffuse Parenchymatous Degeneration of the Nervous System Due to an Intracranial Epidermoid Cyst. B. E. Tomlinson and John N. Walton.

Subacute Necrotizing Encephalopathy in an Acidotic Child. Peter G. Procopis, Brian Turner, and George Selby.

Does Pregnancy Increase the Risk of Multiple Sclerosis ? Uri Leibowitz, Aaron Antonovsky, Rachel Kats, and Milton Alter.

Choreoathetosis in Porto-systemic Encephalopathy. P. J. Toghill, A. W. Johnston, and J. F. Smith.

Long-term Effects of Anterior Temporal Lobectomy on Certain Cognitive Functions. C. B. Blakemore and Murray A. Falconer.

Depressive Symptoms in Parkinson Patients Referred for Thalamotomy. J. W. Warburton.

Metabolic Balances of Copper in Patients with Hepatolenticular Degeneration Submitted to Vegetable and Mixed Diets. Horacio M. Canelas, Francisco Bastos de Jorge, and Waldir A. Tognola.

Plasma and Erythrocyte Magnesium in Huntingdon's Chorea. Laura W. Fleming, Montagu G. Barker, and William K. Stewart.

Book Reviews.

Volume 30, No. 4. Yearly subscription (6 numbers) £4 4s., abroad £4 15s.

BRITISH JOURNAL OF VENEREAL DISEASES

Contents of the September issue are as follows :

Editorial.

Gonococcal Bartholinitis. E. Rees.

Demethylchlortetracycline in the Treatment of Gonorrhoea. R. R. Willcox.

Therapeutic Trial of Trimethoprim as a Potentiator of Sulphonamides in Gonorrhoea. G. W. Csonka and G. J. Knight.

Gonorrhoeal Urethritis in Males Treated with One Oral Dose of Oxytetracycline. D. G. McLone, J. D. Kiley, and J. F. Hackney.

Immunofluorescent Antibody Technique in the Diagnosis of Gonorrhoea by Direct Smears from the Female. J. M. D. Gallwey, C. S. Nicol, and M. Ridley.

Treatment of Relapses and Re-infections in Non-specific Urethritis. A. I Morrison.

Osteolytic Lesions in Early Syphilis. M. F. Bauer and C. M. Caravati, Jr.

General Paralysis of the Insane with Gumma of Skull. S. B. Mahapatra.

Haemagglutination Test utilizing Pathogenic *Treponema pallidum* for the Sero-diagnosis of Syphilis. T. Rathlev.

Fluorescent Treponemal Antibody Inhibition Test. A. E. Wilkinson.

Treponemal Immobilization Tests in Leprosy. H. G. S. Ruge.

Metronidazole in Human Infections with Syphilis. A. H. Davies.

A Note on the Effect of Metronidazole on the Nichols Strain of *Treponema pallidum in vitro* and *in vivo*. A. E. Wilkinson, P. Rodin, J. A. McFadzean, and S. Squires.

Improved Methods of Contact Tracing. B. Muspratt and L. I. Ponting.

Comparison of Amphotericin B and Nystatin Pessaries in *Candida* Infection of the Vagina. G. W. Csonka.

Herpes Genitalis : Clinical and Virological Studies. J. D. J. Parker and J. E. Banatvala.

Book Review. Notes. Abstracts.

Volume 43, No. 3. Yearly subscription (4 numbers) £3 3s., abroad £3 10s.

THORAX

Contents of the September issue are as follows :

Heterograft Aortic Valve Replacement : Initial Follow-up Studies. M. F. O'Brien, J. K. Clarebrough, I. G. McDonald, G. S. Hale, H. S. Bray, and J. F. Cade.

Some Histological Features of Canine Cardiac Transplants. Jacqueline Leandri.

Aspiration Biopsy of Thoracic Lesions. Anthony F. Lalli, Bernard Naylor, and Walter M. Whitehouse.

Cystic Thymomas and Thymic Cysts : A Review. N. H. Dyer.

Functional Disturbance in Hiatal Hernia in Infants and Children. A. R. Chrispin and G. W. Friedland.

Mixed Glandular and Squamous-cell Carcinoma of the Bronchus. D. J. B. Ashley and H. Duncan Davies.

Acute Wegener's Granulomatosis. David Leak and G. P. Clein.

Tridimensional Photographic Reconstruction in a Study of the Pathogenesis of Honeycomb Lung. J. Cortez Pimentel.

Regional and Overall Inequality of Ventilation and Blood Flow in Patients with Chronic Airflow Obstruction. M. C. F. Pain, J. B. Glazier, H. Simon, and J. B. West.

Survey of Spontaneous Pneumothoraces in the Royal Air Force. I. R. Cran and C. A. Rumball.

Congenital Oesophageal Achalasia in the Dog. Richard J. Earlam, Paul E. Zollman, and F. Henry Ellis, jun.

Communication Between the Left Ventricle and Right Atrium. R. S. Barclay, J. M. Reid, E. N. Coleman, J. G. Stevenson, T. M. Welsh, and N. McSwan.

Proceedings of the Thoracic Society.

Volume 22, No. 5. Yearly subscription (6 numbers) £4 4s., abroad £4 15s.

Universities and Colleges

LONDON

Dr. Felix Beck, senior lecturer at University College, Cardiff, has been appointed to the readership in anatomy tenable at the London Hospital Medical College.

The title of reader in oncology has been conferred on Dr. J. G. Azzopardi, in respect of his post at the Royal Postgraduate Medical School.

PH.D.—*In the Faculty of Medicine :* M. J. Creek.

BIRMINGHAM

Appointments.—Dr. P. J. K. Maskery (temporary lecturer, Department of Obstetrics and Gynaecology) ; Dr. S. R. Meadow (senior research fellow, Institute of Child Health) ; Mr. G. D. Oates (part-time lecturer in general surgery for dental students, Department of Surgery).

ROYAL COLLEGE OF PHYSICIANS AND SURGEONS OF GLASGOW

On 4 September the following were admitted Fellows *qua* Surgeon: O. Z. A. El Mannan, K. N. Ramaswamy, M. K. Rana, J. M. Urasa ; Members *qua* Physician: A. P. Agarwal, M. K. Attia, W. R. Chapman, A. W. Dickie, J. F. Mackay, V. Mahadev, J. D. H. Mahony, M. Nuruzzaman, B. K. Pal, A. K. Rastogi, A. Razzaq, S. C. Shah, V. Singh, P. N. Srivastava, C. B. C. Wariyar.

SOCIETY OF APOTHECARIES OF LONDON

L.M.S.S.A.—K. P. Adamson, M. A. M. Ali, I. E. A. Alloub, N. F. Angley, P. B. Arteen, A. R. Crawford, M. A. El Batata, M. I. El Gamal, N. R. H. El-Maraghi, A. R. Erlam, M. A. Gad, E. Gordon, I. Greenhalgh, K. A. S. A. B. Hamadah, C. W. H. Harrison, S. R. Hirsch, I. T. Houghton, S. M. A. Khalik, T. C. Ko, A. Kumar, B. Magnusson, A. K. Mangat, B. S. Mangat, J. F. McCurdy, S. R. Osmani, A. J. Polyzoides, A. F. M. Radwan, K. Ratib, G. F. Salib, E. Savides, B. Sen, R. K. Sharma, R. S. Shenouda, A. K. Shinnawi, Y. M. Sobhy, C. M. Squire, S. G. Tadros Attalla, J. D. Timothy, K. R. Visvanathan, N. R. Youssef, G. C. D. Zaphiropoulos.

DIPLOMA IN INDUSTRIAL HEALTH.—D. Ashcroft, E. Bougas, W. E. Brooke, C. P. Cooper, G. Dalton, D. Dean, P. Drummond, S. Ellison, E. M. Ensor, E. U. Essien, S. H. M. Logan, D. E. Oakley, J. W. Porter, D. G. L. K. Russell, D. B. Sugden, W. G. Thomson.

DIPLOMA IN MEDICAL JURISPRUDENCE (CLINICAL). D. P. Brown, M. E. Glanvill, J. K. Murphy, A. N. Pearson.

DIPLOMA IN MEDICAL JURISPRUDENCE (PATHOLOGY). —R. S. Forrester, P. Pullar.

Deaths

Clyde.—On 20 August 1967, at his home, Neil Provan Rutherford Clyde, M.B., Ch.B., Squadron Leader, R.A.F.M.S. (retired), aged 57.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499. TELEGRAMS: *Aitiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

BRITISH MEDICAL JOURNAL

LONDON SATURDAY 23 SEPTEMBER 1967

Pointers

Leukaemia: Survey in Greater London (p. 755) gives "weak support" for clustering of leukaemia in children. Survey in Lewisham (p. 759) finds no evidence of clustering of the disease in both adults and children. Leader at p. 750.

Colonic Diverticulosis: Transit times of food residues studied radiographically were substantially shorter than normal in patients with diverticula or irritable colon syndrome (p. 760). Study of prevalence of diverticulosis in healthy volunteers in the Oxford area shows incidence of one in three in the over 60's with a female preponderance (p. 762). Letter at p. 800. Leader at p. 751.

Burned Hands: Small children grasping electric-fire elements sustain severe injury requiring prolonged treatment, and the importance of prevention of such accidents is emphasized (p. 764).

Common Cold: Half the volunteers inoculated with "new" respiratory virus developed colds, and half of these subjects showed rising titres of antibody against the virus (p. 767). Leader at p. 752.

Polyarthritis in Leprosy: Syndrome simulating acute rheumatoid arthritis in two patients with erythema nodosum leprosum may have been due to an autoimmune mechanism (p. 770).

Epidemiology of Infectious Hepatitis: Seasonal trend and association between incidence of disease and poor living conditions was noted in a three-year study in Leicester, but no criteria of transmission were elucidated which could assist in preventive measures (p. 773).

Refsum's Syndrome: Three generations of a family investigated but no evidence of biochemical abnormality found in any one except the two patients who were siblings (p. 777).

Case Reports: Peritonitis causing respiratory failure (p. 779); Procainamide incriminated in lupus-like syndrome (p. 780); Hypoparathyroidism and malabsorption syndrome (p. 781); Schizophrenia in a male pseudohermaphrodite (p. 783); Spontaneous haemorrhage from tongue (p. 784).

Today's Drugs: Tolnaftate (p. 785)

Warming Blood: Description of appliance capable of raising blood temperature from 4° to 37° C. in five minutes (p. 787).

Alcohol and Traffic Safety: Proceedings of international conference reviewed (p. 788).

Rehabilitation of Congenital Handicap: Orthopaedic contribution to the management of children successfully operated for myelomeningocele (p. 791).

Twenty-first World Medical Assembly: Report of Madrid conference (p. 795). Leader on this page.

Vocational Training for General Practice: G.M.S. Committee debate (*Supplement*, p. 131). Leader at p. 754.

World Medical Assembly

Last week in Madrid the World Medical Association held its twenty-first General Assembly. Delegations from 32 national member associations attending it included those of the United States, Britain, Australia, Canada, India, Pakistan, most of the countries of Continental Europe, and of countries so far apart as the Philippines, Ecuador, and the Republic of China. After a three-day business meeting there were scientific sessions on the population explosion and birth control and "Medicine and Society." These were appropriate themes for an Assembly in Spain, said Dr. Alfonso de la Fuente in his presidential address, for the Spanish medical profession desired above all to uphold the dignity of the individual and to stress the dangers of weakening family life and of losing sight of the traditional doctor–patient relationship in university medical education. An account of the proceedings appears at page 795.

The W.M.A. is once again showing an interest in some of the more urgent problems of modern medicine. For this much credit must go to the Secretary General, Dr. Alberto Romualdez. Medical ethics has always been a field to which the W.M.A. has contributed fruitfully. Today the relevance of its Declaration of Helsinki,[1] which sets out guiding principles for the clinical research worker, is greater than ever. The public endorsement of these principles by responsible medical bodies in different countries, such as recently in Britain by the Royal College of Physicians of London,[2] is gradually extending their influence. Early in its existence the W.M.A. adopted an International Code of Medical Ethics, and its Declaration of Geneva related the Hippocratic Oath to twentieth-century medicine. Too often the emphasis on the scientific and technical aspects in medical education leaves too little time for students to get a true understanding of the ethical obligations of a doctor. It was therefore welcome that this year the General Assembly, at the instance of the B.M.A., underlined the importance of adequate undergraduate instruction in medical ethics, and recommended that on graduation doctors should be given copies of the Declarations of Geneva (or the Hippocratic Oath) and of Helsinki. This is something that every medical school should be ready to do.

Search for an international definition of the precise moment of death concerns more than just the decision when an organ for transplantation may be removed, important though that is. The problem is sharpened by a physician's ability artificially to maintain circulation and respiration more or less indefinitely. When is it right to switch off the machines? The W.M.A. decided to go on studying this question, helped by evidence collected in a special number of the *World Medical Journal*[3] and the findings of last month's Congress on International Medical Law in Ghent. Already there is legislation in some countries regulating organ transplantation, so the urgency of finding an acceptable definition is plain.

The Assembly showed its awareness of the situation created by world overpopulation and endorsed family planning, though it emphasized that

© *British Medical Journal*, 1967. All reproduction rights reserved.

the final responsibility must be personal. It invited each national organization to study the problem. Those who might consider this a mild achievement, or who regret the absence of any mention of the dangers of excessive child-bearing on the health of the mother or her ability to bring up her family healthily, should remember that the W.M.A.'s resolution had to prove acceptable to doctors from all over the world and of all creeds.

Medical education is another of the W.M.A.'s chosen fields. The Assembly approved plans to hold a fourth World Conference, on the theme "Medical Education: A Collective Responsibility." Under this it is hoped to include the education of paramedical workers. Certainly their increasingly important place in the medical team justifies this. The conference will be held in Europe in 1972, and national medical associations are to be asked to suggest subjects and speakers and to set about raising funds for it. With Britain's entry into the Common Market on the cards, this conference could provide a useful clearing house for information about medical education in Europe, and for this reason alone should evoke the interest of the profession in Britain.

The W.M.A. is a federation of national medical associations from 59 countries, together representing some 700,000 doctors.[4] Through its regional offices and its committee on medico-social affairs, which deals with the payment of doctors and social legislation affecting medical practice, it keeps member associations in touch with developments in other parts of the world. As communications shorten and the world contracts an increasing number of medical questions need debate or action on an international rather than a national or regional level. Some are most appropriately dealt with by the World Health Organization, an intergovernmental body; others by the W.M.A. What the W.M.A. is able to achieve depends on how much its members are prepared to put into it. Medicine is not one of the fields in which Britain has declined as a world force, and the British Medical Association should not be grudging in its support for the W.M.A.

Epidemiological Studies of Leukaemia

The specific aetiology of human leukaemia is unknown. But the leukaemias of some animals (mice and cats) can undoubtedly be transmitted by specific agents with viral characteristics.[1 2] It is therefore tempting to seek evidence for leukaemogenic viruses or infective agents in man.

Such evidence can be obtained in two ways—firstly, by a direct search for identifiable virus particles in leukaemic cells, and secondly by an epidemiological approach aimed at detecting associations of cases of leukaemia in time and place. Though the experimental quest for specific infective agents in human leukaemia has so far been inconclusive,[3] investigators in different countries have reported "clustering"—that is, the close occurrence in place and time of cases of leukaemia. Among the earliest reports are those of C. Aubertin and P. G. Bosviel[4] and C. E. Kellett.[5] More recently G. Knox[6] has presented statistical evidence for clustering in north-east England. These and other observations[7 8] support the possibility that an infective agent might contribute in some way to the causation of human leukaemia. But epidemiological opinion is not unanimous, because some investigators[9–12] have failed to find evidence of clustering.

The detection of significant clustering requires reliable diagnostic and statistical techniques, and in this issue of the *B.M.J.* we publish two more papers reporting careful analyses of cases in the London area. Dr. S. P. Lock and Mrs. Maxine Merrington (page 759) have analysed 115 cases of all types of leukaemia in both adults and children diagnosed between January 1957 and December 1963. The area covered was the former London borough of Lewisham. In the other paper Drs. Morwenna M. Till, R. M. Hardisty, M. C. Pike, and Richard Doll (page 755) report their studies of a larger series restricted to children who developed leukaemia under 10 years of age while resident in Greater London during the period 1952–61. Lock and Merrington confined their analysis to the date and place of residence of the patient at the onset of the disease, while Till and her colleagues extended their study to include information about the patients' date and place of birth. The latter workers point out that factors of aetiological importance are likely to exert their effect a considerable time before the disease becomes clinically apparent, and indeed the experimental work on the animal leukaemias has shown that the disease was most successfully transmitted when the animals were inoculated at or about the time of birth. Thus, if a virus is a cause of the disease, space-time clustering of births rather than time of onset might be more likely.

Both groups of workers used similar statistical techniques but reach somewhat different conclusions. Lock and Merrington could not find evidence of clustering of leukaemia, though their data do not provide evidence against clustering of one or other subtypes of leukaemia. They point out that the same statistical technique has shown clustering of cases of Burkitt's lymphoma in Africa, and furthermore that other statistical methods, while showing clustering of infectious diseases such as poliomyelitis and infectious hepatitis, have failed to show clustering in leukaemia. However, Till and colleagues give some support, though weak, for the general hypothesis that cases of leukaemia tend to occur in clusters more often than would be expected by chance alone, the evidence for clustering being stronger at birth than at onset of the disease. They thus provide some evidence for the possibility of the existence of a contagious agent in human leukaemia.

The difference between the conclusions reached in the two papers are probably the result of differences in the data analysed. The negative findings of Lock and Merrington,

while statistically valid, would not necessarily exclude the existence of an infectious agent in human leukaemia. If, on the other hand, leukaemia is a truly infectious disease, it would be more useful to look for an association between the date and place of residence of one child during the period of infectivity and that of another child during the period of susceptibility to the disease. This suggestion might be extended to a study of the parents of affected children, since they will have had the closest and longest contact with the child. But this illustrates the complexity of the epidemiological problem, since nothing is known of these presumed periods of infectivity and susceptibility, and if the proposition is valid the collection of such information will depend on the development of more refined analytical methods.

The hypothesis that human leukaemia is a contagious disease is appealing, and the evidence from the animal leukaemias provides in itself sufficient reason for the experimental approach in studying the human disease. Isolation of a causative organism offers the hope of rational and effective treatment, both immunological and chemotherapeutic, which in the final analysis can be achieved only in the experimental laboratory. But apart from providing evidence for infective agents the epidemiological approach might point to environmental factors which could be controlled. If leukaemia is an infectious disease it must be one of a very special kind, and perhaps the epidemiologist will discover some of these peculiarities. Moreover, in view of its potentially useful epidemiological value the history of all cases of leukaemia should be as detailed as possible and should include information on exposure to other human infections or prolonged contact with animals, insects, and chemical agents.

Diverticular Disease of the Colon

Maxwell Telling and O. C. Gruner,[1] of Leeds, gave an exhaustive account in 1917 of the natural history of diverticulosis of the colon. But not until recently was much attention paid to the aetiology of this common and increasingly important condition.

The diverticula may occur anywhere in the colon but congregate especially in the sigmoid. They lie in two columns alongside the lateral taeniae coli, where they are often overlapped by the appendices epiploicae. Unlike diverticula of the small bowel, which project into the mesentery, the colonic diverticula never protrude primarily into the mesocolon. The distribution of colonic diverticula corresponds precisely to the points of penetration of the blood vessels into the bowel wall, as H. Drummond[2] first showed, and they doubtless produce areas of weakness in the colonic musculature.

Basil Morson[3] made an important contribution to our knowledge of the aetiology of this disease by taking attention away from the saccules themselves and concentrating more on the colonic wall. He reported his investigations of 173 specimens of colon removed for diverticulitis at St. Mark's Hospital, London. Of these, 112 (64%) showed evidence of diverticulitis, which was extensive in 67 and focal in 45 cases. In 61 specimens there was no inflammation at all, and 5 of these indeed did not even show diverticula, yet in all cases operation had been performed because diverticulitis had been diagnosed on both clinical and radiological evidence. However, all the specimens showed striking abnormalities in the muscle wall. The taeniae coli were thickened and almost cartilaginous; the circular muscle was also thickened and arranged in concertina-like folds, with the orifices of the diverticula opening between their corrugations. This thickening of the plain muscle appeared to be a shortening rather than a true hypertrophy, and it accounted for the characteristic redundancy of the mucosa, which was itself thrown into folds and appeared to contribute to the obstruction so common in this condition.

N. S. Painter and S. C. Truelove[4] [5] have shown by cineradiography and other methods that the resting pattern of pressures in the normal sigmoid colon and in the colon affected by diverticulosis is the same, but very high pressures develop in the diseased segments in response to morphine and prostigmine. In these cases cineradiography showed that the colon was divided by contraction rings into a series of segments whose outflow was obstructed, and the consequent localized high pressures were seen on occasions to distend the related diverticula considerably. There is thus in diverticular disease good evidence of abnormal segmentation and the generation of high pressures after certain drugs, together with histological proof of an abnormal circular muscle. Investigation of other causes of excessive segmentation—diet, drugs, and purgatives, for example—may lead to important information on the pathogenesis of diverticulosis. Dietary factors may well be of importance. Diverticulosis is a common condition in so-called civilized communities which enjoy a refined diet and is extremely rare in less sophisticated populations living on a bulky vegetable diet.[6]

Not only are we still ignorant about the exact aetiology of diverticulosis, but also there is a surprising lack of accurate information on its frequency in the population as a whole. The incidence has been calculated from barium-enema studies on hospital patients and from post-mortem examinations, both highly selected population groups. However, the investigations have certainly given some useful information. Thus T. P. Dearlove,[7] in his extensive necropsy study of nearly 7,000 cases at the Royal Adelaide Hospital, found that diverticulosis was almost unknown under the age of 40 years. In the 40s the incidence rose to approximately 1%, in the 50s to 1.7%, in the 60s to 3.5%, and in patients over the age of 70 years to 7%. Large series of patients examined by barium enema have shown diverticula in 5 to 10% of the cases.

In this issue of the *B.M.J.* Dr. Truelove together with Drs. O. N. Manousos and K. Lumsden present an important study of a barium follow-through examination on 109 persons without gastrointestinal symptoms (page 762). Twenty were found to have diverticula. Above the age of 60 15 out of 43 people had them (about one in three), and below that age 5 out of 66. None of the 14 people under the age of 40 had any diverticula. The condition was more common in women than in men. Though the numbers are comparatively small, the study is of particular value in that it deals with a population either healthy or at least completely free of gastrointestinal symptoms. It therefore gives a good indication of the incidence of colonic diverticula in the general population in Britain.

As to the aetiology of colonic diverticula, it is interesting that these workers, in a separate study reported at page 760, have found the colonic transport time to be considerably shorter in patients with diverticula than in normal persons, and the same fast transit time was noted in patients with the irritable colon syndrome. They conclude that their evidence supports the hypothesis that incoordinated colonic activity is the basic abnormality in diverticular disease of the large bowel.

New Respiratory Virus

The complex aetiology of acute respiratory disease has been gradually revealed during the past fifteen years with the discovery of one after another "new" virus. Each one in turn has been studied for its pathogenesis in man and eventually allotted a place in one of the various virus families on the basis of its physical, chemical, and morphological properties.

The myxovirus family, besides having the true influenza viruses A, B, and C, has had added to it five different parainfluenza viruses and probably also the respiratory syncytial virus. The adenovirus family contains 31 different serotypes, and the picornavirus family, the home of poliomyelitis, E.C.H.O., and Coxsackie viruses, now shelters about 80 rhinoviruses, all isolated from patients with common colds.

The veils of mystery surrounding respiratory illness are gradually being lifted. With the right technique one of these many organisms can increasingly be found to be the cause of disease. However, there still remains a fair proportion of cases in which nothing can be found to account for the patient's symptoms and the hunt is by no means over.

A new technique developed by B. Hoorn and D. A. J. Tyrrell[1] involved the use of fragments of trachea and nasal epithelium from the human embryo to provide an "organ culture" for the viruses. This procedure was found to increase the frequency of virus isolation from patients with colds to a considerable extent. The viruses grown in this way were sometimes familiar ones which could be grown in tissue culture, but it was quickly recognized that there were others which were clearly multiplying in the organ cultures and producing colds in volunteers, but refusing to behave like other viruses in ordinary tissue cultures.

D. Hamre and J. J. Procknow[2] had earlier isolated from students with colds some other fastidious viruses, which, though they grew in tissue culture, did so only with special techniques. J. D. Almeida and Tyrrell[3] then put these fastidious viruses and those grown on organ culture under the electronmicroscope and discovered not only that the two groups were morphologically similar but that they differed from the usual human respiratory viruses. Though the new viruses contain R.N.A. and are destroyed by ether, and have therefore some characters of the myxoviruses, in their structure they can be readily distinguished. In place of the fine frill surrounding the myxovirus particle well-spaced wedge-shaped projections can be seen in these viruses round the circumference of the particle. It was also noted that these human viruses were apparently identical in structure with a virus known to cause infectious bronchitis in fowls and with one causing hepatitis in mice.

So far as is known neither of these last two viruses is pathogenic for man, but antibody to mouse hepatitis virus has been detected in human sera, and J. W. Hartley and colleagues,[4] investigating respiratory illness among military recruits, detected during three successive winters a wave of serological changes suggesting that the recruits had experienced an epidemic of infection with mouse hepatitis virus or with a virus of a similar antigenic composition.

A further six strains of this virus with the new look were isolated by K. McIntosh and colleagues,[5] who extended their studies of respiratory disease to include organ culture. Since they had not included symptomless controls in their series, they were unable to be certain that the viruses were in fact responsible for the disease. The evidence was certainly suggestive, as was that obtained by Hamre and Procknow,[2] whose isolates were in every case but one from patients with illness. But it was clear that a strain would have to be tested in human volunteers under controlled conditions if this point was to be decided for certain.

In this issue of the *B.M.J.* Mr. A. F. Bradburne, Dr. M. L. Bynoe, and Dr. Tyrrell produce evidence that this virus has a pathogenic role (page 767). Twenty volunteers given saline remained healthy, whereas half of those given virus developed a fairly typical common cold with a profuse nasal discharge, mild fever, and a significant rise in serum antibody to the virus.

The connexion of what must now be recognized as a human respiratory pathogen with the morphologically identical fowl and mouse viruses has still to be determined. Preliminary results suggest they are serologically distinct, and it appears that we have a whole new virus family with possibly multiple serotypes. Another veil is down; our ignorance is less; but every additional virus must dampen our hopes for a vaccine to control acute respiratory illness.

Overwhelming Infection after Splenectomy

A late complication of splenectomy is fulminating generalized infection. This hazard was first reported in 1952 by H. King and H. B. Shumacker in five infants who had undergone splenectomy for hereditary spherocytosis.[1] Though the relationship between splenectomy and overwhelming infection has been doubted,[2 3] most people agree that there is a significant connexion between the two. Children are more vulnerable than adults, and most cases of infection occur within the first few years of splenectomy.[4 5]

A. J. Eraklis and his colleagues[6] have recently reviewed 467 cases of splenectomy followed up for at least three years, and in many instances up to ten years. They found that about 5% of patients died of overwhelming infection, and that the incidence of this disaster depended on the antecedent condition. No patient whose spleen was removed because of traumatic rupture, idiopathic thrombocytopenic purpura, extrahepatic portal-vein thrombosis and portal hypertension, or localized tumour died of infection. The incidence was very low in those with hereditary spherocytosis and aplastic anaemia, but it was higher in cases of thalassaemia major, cirrhosis of the liver, histiocytosis (Letterer–Siwe disease), and lipidosis (Niemann–Pick disease and Gaucher's disease). Four patients with the Wiscott–Aldrich syndrome all died of infection after splenectomy. The condition is characterized by thrombocytopenic purpura, recurrent infections, and eczema, and there is often an associated dysgammaglobulinaemia.[7] It is important to distinguish this condition from idiopathic thrombocytopenic purpura, for the former does not respond to splenectomy.

[7] Aldrich, R. A., Steinberg, A. G., and Campbell, D. C., *Pediatrics*, 1954, **13**, 133.

A. J. Eraklis and his colleagues found that the incidence of infection was greatest in children below the age of 4 years, but it was not especially high in infancy. Most of the deaths occurred within four years of splenectomy, but in one case the interval was nine years. The infection was usually overwhelming meningitis with septicaemia or else a fulminating bout of pneumonia, and the infecting organisms were most often the pneumococcus, meningococcus, and *Haemophilus influenzae*.

The role of the spleen in preventing bacterial infection is unknown. Perhaps by virtue of its high content of reticuloendothelial cells it acts as a filter for circulating bacteria. It is in patients with underlying diseases affecting the reticuloendothelial system—for example, the lipidoses and histiocytosis—that splenectomy is most often followed by infection. But, whatever the mechanism, it is advisable to treat any pyrexial condition in a patient who has undergone splenectomy with particular concern.

Obstetric Forceps or Vacuum Extractor?

Foetal distress in labour is the inviolable indication for immediate delivery, and in this situation the sooner the baby is born the better. However, the obstetrician must not only exercise his skill to deliver the baby from its obstetric dilemma but he must also protect the baby from any damage or delay caused by the operation itself. In modern obstetric practice a choice must be made between forceps and the vacuum extractor—each instrument can be a life-saver, but each has its own operative complications.

Advice on the choice of instrument has often been confusing in the past. Now, J. G. Schenken and D. M. Serr,[1] who are practising obstetricians, have recorded their experience of the definitive indications for the use of each instrument, and, indeed, they found that these indications rarely overlapped.

It is not merely tradition that makes the obstetric forceps the preferred instrument for the management either of delay in the advance of the foetal head or of foetal distress in the second stage of labour. Firstly, the delivery will be quicker, because the trained obstetrician is able to introduce the forceps deftly and apply them safely round the foetal head within a matter of minutes, whereas the preparations for the use of the vacuum extractor take at least a quarter of an hour—setting it up, applying the cup, and building up the pressure. Secondly, delivery is safer because a doctor cannot hope to apply the forceps correctly and effectively until he has checked the position of the occiput. The danger with the cup is that it can be applied to the foetal scalp irrespective of the position of the occiput—and if it is applied to the skull in the occipito-posterior position the unwary obstetrician can lead himself into either a failed or a difficult vacuum extraction, and so expose the child to risk of cerebral haemorrhage. Properly applied obstetric forceps should not damage the brain, and certainly they should not lacerate the scalp, whereas damage to the scalp by necrosis at the site of the application of the vacuum cup is not uncommon, particularly if it is applied for any length of time. Furthermore, if the cup is suddenly and unexpectedly released from its attachment during traction petechial haemorrhage on the surface of the baby's brain can easily result.

The place of the vacuum extractor is pre-eminent in facilitating delivery where foetal distress has occurred or there has been delay in progress of the first stage of labour. The cup may be slipped through a cervix which is half-dilated or more, then with firm, steady traction the head may be pulled down within the pelvic cavity, so facilitating cervical dilatation. The application of forceps is completely contraindicated under these circumstances, and such a procedure would invite failure and disaster. Vacuum extraction with an undilated cervix should be undertaken only by a skilled obstetrician and always in an obstetric hospital, where if foetal distress occurs a caesarean section may be performed with the least delay.

Neither instrumental technique has any place if the foetal head is not engaged in the pelvis, or indeed if there is any cause to suspect disproportion which might necessitate caesarean section. The vacuum extractor has no place on the district or in a general practitioner maternity unit. But the use of the obstetric forceps for assisting a delivery in the second stage will always remain one of the most valued skills of the general practitioner obstetrician.

Menace of Smoking

On 18 July the Minister of Health invited the leaders of the tobacco industry to consider whether they could agree on proposals for limiting the sales promotion of cigarettes. Last week they informed the Minister that they had been unable to reach agreement on a scheme of limitation. Consequently, as the Ministry of Health has announced, the Minister "thanked them for the earnest efforts that had been made by all concerned" and said that the Government would consider the position.

In 1965 there were over 26,000 deaths from cancer of the lung in England and Wales, and the figures for Scotland and Northern Ireland bring the total up to about 30,000 for the United Kingdom. The evidence can no longer be doubted that the great majority of these deaths were due to cigarette smoking. Since E. L. Wynder and E. A. Graham[1] and A. Bradford Hill and R. Doll[2] first clearly showed the association between smoking and cancer numerous independent studies have confirmed and amplified their conclusions. In addition, the relationship of smoking to chronic bronchitis and emphysema is well proved.

Now a report coming from the U.S. Public Health Service[3] brings up to date the one it issued three years ago.[4]

The recent studies increasingly suggest that smoking, in addition to its undoubted connexion with lung cancer, plays some part in the development of cancer of the mouth, larynx, oesophagus, and possibly pancreas. But no association with cancer of the stomach has been found despite investigations into the question. Epidemiological, clinical, and experimental data also point to a relationship between smoking and cancer of the bladder, though whether it is causal remains so far uncertain. Evidence continues to accumulate showing that cigarette smokers, both men and women, are much more liable to coronary artery disease than are non-smokers. Moreover, a reduction in the risk follows cessation of smoking. According to the report, too, additional evidence strengthens the association between cigarette smoking and cerebrovascular disease.

The smoking of tobacco, and especially of cigarettes, is surely the greatest menace to the public health of our time, causing death and disability on a scale reminiscent of the epidemic diseases of earlier centuries. But a dilemma faces any Government that attempts to diminish the scourge of smoking, for it is not, like the epidemics, a communicable disease—except by example—so that the general public might not be as willing to accept compulsory measures of restriction as they were in the case of infectious diseases. Moreover, special difficulty in educating the public comes from the long interval between a man's beginning to smoke and his death from lung cancer—usually some decades. If the chances of a smoker contracting cancer were the same as now but the interval before death was only some months it is scarcely conceivable that cigarettes would be marketed at all, or, if they were, that legislation would be long delayed to prohibit them altogether. Since the Government is unlikely to adopt that course at present, it must consider others. The measure most often canvassed is a complete ban on the advertising of cigarettes. If this and other restrictions are imposed they will need to be supplemented by much more thorough educational campaigns than have been carried out so far, directed especially to young people[5] and with a skill that will communicate firm conviction rather than mere knowledge of the harm that follows smoking.

Good General Practice

As reported in the *Supplement*, the General Medical Services Committee has in the main approved its advisory committee's report on vocational training for general practice. Any criticism was mostly of details and not of principles. The report has been sent with the G.M.S. Committee's blessing to the Royal Commission on Medical Education and to the Central Committee on Postgraduate Medical Education, set up in June, under the chairmanship of Sir Robert Aitken, by the universities with medical schools and the medical colleges of England and Wales and Scotland.[1] This Committee, which has now incorporated " (Great Britain) " in its title[2] in recognition of its concern with Scotland as well as with England and Wales, has already discussed the organization of medical training in the first three years after registration. Also published early this month were the Royal College of General Practitioners' views[3] on how its earlier proposals for vocational training should be implemented.

There is no longer any real dispute about the need for vocational training for general practice in the same way as it is needed for other specialized branches of medical practice. The only remaining questions are on how it should be done and when it should begin. Vocational training must be seen as part of the whole of medical education, and it cannot be considered separately from postgraduate education. Further events must await the report of the Royal Commission on Medical Education, expected early next year. It may be supposed that the Commission has had the benefit of the views of the Central Committee on Postgraduate Medical Education in addition to those of the General Medical Council, the colleges, the B.M.A., and the other bodies that have given evidence to it. Those who are anxious for progress will therefore be looking to the Royal Commission's recommendations to provide the impetus that is needed.

Not surprisingly, the views of the Royal College of General Practitioners and of the G.M.S. Committee's Advisory Committee on Vocational Training and Continuing Education for General Practice were very similar. They shared many members in common, and also vocational training for general practice is now so old a concept that ideas on it have had plenty of time to crystallize out. If the trainee practitioner scheme has not been the success that was hoped for it has certainly provided a source of valuable experience on which to build. So also have some other schemes, notably the Wessex experiment in training for general practice. Against this background of general agreement some cautionary notes sounded in the G.M.S. Committee's debate should be heeded. The demands on, in some cases, seriously overworked doctors to provide medical care for patients are certain to conflict with what those who have to administer the Health Service are bound to consider as the less pressing needs of medical education. The essence of traineeship is to be a learner first and a doer—a pair of hands—second. The urgent need of the Health Service is for more and more pairs of hands. For this reason the responsibility for vocational and for all postgraduate training must surely be with educational committees. An organization with the Central Committee on Postgraduate Medical Education (Great Britain) at its head seems ideal for the purpose. Likewise, it would be better to regard vocational training as a university responsibility and not a Health Service one. This implies that the money for it should come mostly from the University Grants Committee and not from the Ministry of Health. This is something the medical profession should lay stress on.

Short of making vocational training compulsory—and the wisdom of taking so big a step to begin with is questionable—participation in any scheme must depend on the incentives which prospective general practitioners are offered. They will not enter a scheme if they suffer disadvantage from their keenness. They must be paid properly while they train, and afterwards their added skills must be rewarded. The current vocational training payments in general practice are derisory. In this, as in other respects, the country must be prepared to pay for a good medical service or to have a poorer one. But there will be no inducement to young doctors to add three to four years to their training if they cannot use their skills when they go into practice. Vocational training is important, but it would be putting the cart before the horse to train first-class doctors for third-class working conditions. Emigration would increase, not decrease. If general practice is to attract recruits it must offer them the facilities for practising good medicine.

Childhood Leukaemia in Greater London: a Search for Evidence of Clustering

MORWENNA M. TILL,* B.A., M.B., D.C.H.; R. M. HARDISTY,* M.D., M.R.C.P.; M. C. PIKE,† PH.D.
RICHARD DOLL,† M.D., D.SC., F.R.C.P., F.R.S.

Brit. med. J., 1967, 3, 755–758

The suggestion that viruses might play a part in the causation of leukaemia has reawakened interest in the epidemiology of the disease, and has led many investigators to search for evidence of its occurrence in clusters. Little attention was paid to Kellett's (1937) original report of an epidemic in the area around Newcastle upon Tyne; but at least 19 similar reports have been made in the past eight years. Heath, Manning, and Zelkowitz (1964) noted 13 besides their own, and other reports have been made by Knox (1964), Meighan and Knox (1965), Mustacchi (1965), Dowsett (1966), and Mainwaring (1966). It was not until 1963, however, that the importance of distinguishing between clustering in space, in time, and in space and time considered together was fully appreciated (Knox, 1963), and not until the following year that a serious attempt was made to assess the probability that an observed cluster in both space and time could occur owing to chance alone (Knox, 1964).

Knox (1964) noted the addresses and dates of onset of all cases of childhood leukaemia in Northumberland, Durham, and part of Yorkshire over the ten-year period 1951–60 and found that there was a statistically significant excess of pairs of affected children in whom the onset of symptoms began before their sixth birthday, who lived within one kilometre of each other, and in whom the dates of onset were within 60 days. The implications of this finding, however, are limited by the fact that the clustering was found only for one clinical subgroup of the cases and for limited space and time intervals, and that those characteristics which defined the positive cluster were thrown up by the investigation itself and not by a preceding hypothesis. Thus Knox's findings should be regarded as constituting a sound basis for formulating a hypothesis to be tested against further observations and not as proof of the existence of real clustering. We have therefore sought to test the hypothesis by examining the distribution of childhood leukaemia (defined for this study as leukaemia with onset of symptoms before 10 years of age) in another area.

From the point of view of theoretical oncology the concept that the *onset* of leukaemia should occur in clusters is not particularly attractive, as factors of aetiological importance are likely to exert their effect a considerable time before the disease becomes clinically apparent. Clustering in space and time of the births of the leukaemic children would seem to be a much more likely event if a virus played any part in the production of the disease. We have therefore also looked into this possibility.

Material

Copies of the death entries were examined of all the children who died of leukaemia under 15 years of age during the ten years 1952–61 and who were resident in Greater London at the time of their death. Only children in whom the primary cause of death was certified as leukaemia were included and no attempt was made to find children who, though born or developing the disease in Greater London, were resident elsewhere when they died. Altogether 618 children were studied. For each of these the hospital case records were sought and the clinical and haematological details reviewed. In addition Dr. Alice Stewart allowed us access to all the data she had collected on these children during the Oxford Survey of Childhood Malignancies.

As a result of this review 135 children were excluded: (*a*) 105 because they were more than 10 years old when symptoms first occurred; (*b*) 11 because they were born and living outside Greater London at the time of onset of symptoms; and (*c*) 19 because the diagnosis of leukaemia was not confirmed—in eight the hospital records suggested that death was due to some other cause, in two the diagnosis rested solely on the post mortem findings, which in our opinion were inconclusive, and in nine the medical records had been destroyed or could not be traced.

Birth certificates were sought for the remaining 483 children and were obtained for all but 18—6 who were known to have been adopted, 9 who were known to have been born abroad, and 3 others.

The following data were used for the analysis:

(1) *Date of onset,* taken as the date of the first symptoms referable to leukaemia in the medical records. This was always recorded as a specific day even though the exact choice of date was known to be to some extent arbitrary. For example, "one month ago" was taken to mean exactly one calendar month before the date on which the history was recorded; symptoms dating from a specified month were recorded as starting on the 15th of the month, and symptoms said to have been present for "several weeks" or "several months" were dated from three weeks or three months previously. The onset in one infant in whom leukaemia was present at birth was taken as three months antenatally.

Table I shows the frequency distribution of the lengths of history recorded according to these conventions. In each case the length of history was taken to be the time between the onset and the date of the first relevant medical record, even though a firm diagnosis of leukaemia was not always made until some time later. In 235 cases the history was of four weeks or less or was referable to an exact date, and in these the date of onset was probably accurate to within a week. In a further 126 cases the duration recorded was "one month," was referable to a month by name, or was not more than two months with symptoms of abrupt onset, and in these the date of onset was probably accurate to within two weeks. Thus three-quarters of the dates of onset are likely to have been accurate to within two weeks; the remainder were probably accurate to within two months and usually to within much less.

* The Hospital for Sick Children, Great Ormond Street, London W.C.1.
† Medical Research Council's Statistical Research Unit, University College Hospital Medical School, London W.C.1.

(2) *Address at time of onset of symptoms,* taken from the medical records. In the absence of specific evidence to the contrary this was taken to be the same as the address at the time of the nearest subsequent medical attendance. Two children were living outside Greater London at the time of onset and are therefore excluded from analyses of clustering at this stage in the course of the disease. For 252 of the remaining children (52%) the address at onset was the same as the place of residence at birth.

TABLE I.—*Number of Children With Different Lengths of History at Presentation (Onset Under* 10 *Years of Age)*

Length of History (in weeks)	No. of Children	Cumulative Percentage of Total
2 or less	122	25
-4	84	43
-6	113	66
-8	68	80
-13	42	89
-26	39	97
More than 26	15	100
All durations	483	100

(3) *Date of birth,* taken from the birth certificate when available.

(4) *Place of birth and home address at birth,* taken from the birth certificate. Of the 465 children whose birth certificates were traced, 42 were born outside Greater London and 28 had home addresses outside Greater London. The numbers of children for whom it was possible to examine evidence of space-time clustering in relation to date and place of birth and date of birth and home address at birth were therefore reduced to 423 and 437 respectively. The map references of all addresses were found correct to within 100 metres. When the child was born in hospital the middle of the hospital was taken to give the map reference.

(5) *Cytological and clinical type of leukaemia,* determined after a review of the reports of peripheral blood counts, marrow examinations, and clinical and post mortem findings. Three hundred and seventy-four cases were classified as acute lymphoblastic leukaemia; 52 as acute myeloblastic leukaemia; 16 as acute monocytic leukaemia; and 3, in which abnormal erythroblasts were the predominating cell type, were classified as acute erythroleukaemia. Four children aged 5 to 9 years showed blood, marrow, and clinical findings typical of the adult form of chronic granulocytic leukaemia, and the series also included two children previously described as having the juvenile form of the disease (Cases 1 and 2 in the series described by Hardisty, Speed, and Till, 1964) and eight other children aged 2 months to 2 years, so closely resembling these in their haematological and clinical features that it seemed justifiable to classify them in the same group—making a total of 14 cases of chronic granulocytic leukaemia. In 15 cases it was not possible to ascertain the cytological type, though there was no doubt about the diagnosis of acute leukaemia, and these were classified as acute unspecified leukaemia. Finally, nine cases in which the evidence of leukaemia was suggestive but incomplete were unclassified.

The distribution of cases by type, sex, and age at onset is shown in Table II.

Results

Clustering in Space

The distribution of cases throughout the Greater London conurbation is shown in Table III. The population at risk has been taken to be the mean of the population under 10 years of age at the censuses of 1951 and 1961. At these dates the Greater London area was divided into 95 London boroughs and municipal boroughs in the home counties, and the populations of most of these areas were too small for individual examination. The areas have therefore been combined to provide units that correspond as nearly as possible to the boroughs of the new Greater London Council. The highest incidence is recorded in Sutton, Epsom, and Ewell (7.7 per 100,000 children per year) and the lowest in Hounslow (1.7 per 100,000 children per year).

TABLE III.—*Incidence of Leukaemia in Different Parts of Greater London (Children With Onset Under* 10 *Years of Age)*

Borough	Incidence per 100,000 Children per Year	No. of Cases	
		Observed	Expected at Rate for Whole Area
*City of Westminster	3·9	11	11·8
Camden	3·8	11	12·1
Islington	4·9	19	16·5
Hackney	4·2	16	16·2
Tower Hamlets	4·8	16	14·2
*Greenwich	5·2	18	14·7
Lewisham	3·2	14	18·4
Southwark	3·2	16	21·0
*Lambeth	4·2	14	14·2
*Wandsworth	4·8	29	25·6
Hammersmith	3·3	10	12·8
Kensington and Chelsea	3·9	9	9·8
*Waltham Forest	6·0	22	15·5
*Redbridge	3·3	16	20·1
*Barking	4·9	14	12·1
*Newham	2·8	12	17·8
*Bexley	4·9	19	16·3
*Bromley	5·0	18	15·2
Croydon	5·4	25	19·6
*Sutton	7·7	28	15·5
Merton	4·7	12	10·8
*Kingston-on-Thames	4·0	11	11·7
Richmond-on-Thames	3·9	9	9·8
*Hounslow	1·7	6	15·0
Hillingdon	3·8	13	14·6
Ealing	5·0	20	17·0
Brent	4·2	17	17·0
*Harrow	5·0	16	13·4
*Barnes	3·9	19	20·7
Haringey	3·1	11	15·1
Enfield	2·7	10	15·9

* Boundaries do not correspond exactly with the borough of this name in the new Greater London.

Inspection of the map of London shows that there is no tendency for high and low areas to lie close to one another, and statistical analysis reveals that the amount of variation between the boroughs is no more than can easily be attributed to chance ($\chi^2=33.4$, $n=30$, $P=0.3$).

Clustering in Time

Table IV shows the distribution of cases by year of onset, separately for the two principal cytological types, and for cases with ages of onset under and over 6 years. As the data are derived from information about deaths in the years 1952–61 a relatively small number of cases is to be expected in 1960–1. Between 1952 and 1959 the annual number shows little variation.

Table V shows the distribution of cases by month of onset. No seasonal peaks are evident, neither for all cases taken together, nor for lymphoblastic cases alone, nor for children with onset under 6 years of age; in all groups the numbers arising in summer and winter—defined by Knox (1964) as May to October and November to April—are practically identical.

TABLE II.—*Number of Children with Different Types of Leukaemia by Sex and by Age at Onset (Onset under* 10 *Years of age)*

Type	Age (in years) at Onset										Sex		Total
	0	1	2	3	4	5	6	7	8	9	M	F

Clustering in Space and Time

The data were examined for evidence of clustering in both space and time together by Knox's (1964) method—that is, by seeing whether pairs of cases that occurred close together in space also occurred close together in time. All cases were examined as one set, and separately in various subsets consisting of lymphoblastic cases only, cases with onset under 6 years of age, and cases with deaths under 6 years of age. Clustering was looked for in regard to place and date of onset, place and date of birth, and place of mother's residence at the child's birth and the child's date of birth. Subsets of data relating to date of birth were also examined for children born in 1952–5, to ensure that all members of a cohort who died under 6 years of age were included.

Since the data were derived from information about deaths in 1952–61 the number of cases known to have had their *onset* in years before 1952 and in 1961 (the last year of the period studied) must be deficient; examination of the interaction between date and place of onset was therefore limited to the period 1952–60.

The various sets of data used and the types of interaction examined are shown in Table VI. In each case evidence of clustering was looked for over all combinations of 12 critical times apart (15, 30, 45, 60, 75, 90, 105, 120, 135, 150, 165, and 180 days) and 12 critical distances apart (0.25, 0.5, 0.75, 1, 1.25, 1.5, 1.75, 2, 2.5, 3, 3.5, and 4 kilometres). In only three instances was any evidence of positive clustering found —that is, significantly more pairs of cases within the critical times and distances of one another than would be expected from the whole subset of data under examination. No statistically significant clustering was found in the subset originally specified by Knox—that is, clustering of onsets among children in whom the disease began before their sixth birthday—nor was any significant clustering found when the examination of this subset of children was limited to those with lymphoblastic leukaemia.

Details of the amount and character of the clustering in the three instances in which statistically significant results were obtained are shown in Table VII. Each subset includes lymphoblastic cases only. In two instances there is weak evidence of clustering of times and places of onset; the excess numbers of pairs are small (3 to 5), but it is notable that the distances and times within which the cases occurred (¾ km. and 60–75 days) are similar to those recorded by Knox (1964). In the third subset the clustering relates to the date of birth and the mother's place of residence when the child was born. The probability of as many or more clusters occurring due to chance alone is lower and the excess numbers of pairs are somewhat greater (9 to 24), but the clusters are less striking in that the distances in both time and space separating individual members of each pair are much greater.

Four sets of data were also examined for clustering at the onset of the disease by an alternative method suggested by David and Barton (1966). Each set consisted of cases with onset in the period 1952–60, the groups being composed of (*a*) all children, (*b*) children with lymphoblastic leukaemia, (*c*) all children with onset before their sixth birthday, and (*d*) children with lymphoblastic leukaemia with onset before their sixth birthday. In none of the groups was any evidence of clustering obtained. Comparison of the results obtained by these two methods showed that David and Barton's (1966) method was less sensitive to the presence of small clustering in this type of material and the method was not used to examine the other sets.

Discussion

Our data have failed to provide clear evidence in support of Knox's hypothesis that leukaemia in children under 6 years

TABLE VI.—*Examination Made for Evidence of Space–Time Clustering*

Subset of Leukaemic Children	Type of Interaction	No. of Children
All with onset 1952–60	Date and place of onset	444
All with onset 1952–60 before 6th birthday	Date and place of onset	315
All with onset 1952–60 and death before 6th birthday	Date and place of birth	282
All with onset 1952–60 and death before 6th birthday	Date of birth, place of residence at birth	292
All with birth 1952–55 and death before 6th birthday	Date and place of birth	116
All with birth 1952–55 and death before 6th birthday	Date of birth, place of residence at birth	118
*Lymphoblastic with onset 1952–60	Date and place of onset	346
Lymphoblastic with onset 1952–60 before 6th birthday	Date and place of onset	252
*Lymphoblastic with onset 1952–60 and death before 6th birthday	Date and place of onset	230
Lymphoblastic with onset 1952–60 and death before 6th birthday	Date and place of birth	224
*Lymphoblastic with onset 1952–60 and death before 6th birthday	Date of birth, place of residence at birth	232
Lymphoblastic birth 1952–55 and death before 6th birthday	Date and place of birth	89
Lymphoblastic birth 1952–55 and death before 6th birthday	Date of birth, place of residence at birth	91

* Evidence of statistically significant clustering, see Table VII.

TABLE VII.—*Categories of Leukaemia with Significant Evidence of Clustering in Space and Time*

Subset of Patients	Interaction	No. of Children	Critical Time (Days)	Critical Distance (Kilometres)	No. of Pairs	Expected No. of Pairs	Standard Deviation	Probability*
Lymphoblastic leukaemia onset 1952–60	Date and place of onset	346	60	0·75	8	4·60	1·96	0·051
			75	0·75	10	5·06	2·20	0·034

			180	3·00	88	69·23	8·02	0·014
			180	3·50	116	91·83	9·24	0·007
			180	4·00	139	115·70	10·36	0·017

* Probability of an equal or greater excess number of pairs being observed by chance from the Poisson distribution.

of age tends to occur in clusters, children who live within one kilometre of each other tending to develop symptoms of the disease within 60 days of each other. It should be noted, however, that 9 of the 10 children who formed the clusters in Knox's original data had lymphoblastic leukaemia and all developed their disease under 4 years of age; and our data provide some some weak evidence of clustering at the onset of the disease within similar critical limits (¾ km. and 75 days) in children who *died* of lymphoblastic leukaemia under 6 years of age (in fact the ages of the children at onset were under 4 years in 10 out of 12 cases). In view of the fact that Knox was studying an area with a population scattered over large and small towns and villages, whereas we were studying a single conurbation, this degree of similarity between the results is notable and provides some weak support for the general hypothesis that cases of leukaemia do tend to occur in clusters more often than would be expected by chance alone.

In our data the strongest evidence of clustering occurs with date and residence at birth, and a leukaemogenic agent is presumably more likely to be effective at or around this period than at any other in the child's life. The dimensions of the cluster are, however, too large to suggest a single focus of infection (4 km. and 180 days), and, as with Knox's (1964) original data, the statistical tests employed do not have the significance normally attached to them. A large number of possible critical times and distances were examined, and, logically, the analysis does no more than allow us to pick out a new hypothesis, which can be tested only on further data.

With the methods now available we have been able to look for clustering only in relation to a few specified periods in the natural history of the disease, and these would not necessarily be the most relevant if the disease was truly contagious. Under these conditions it would be more appropriate to look for interaction between, say, the date and place of residence of one child during his period of infectivity and the place of residence of another child during a period of susceptibility—which might be several years before the disease was clinically apparent. Without knowledge of the periods when infectivity and susceptibility occur, this is a problem of some complexity. A general method of searching for interaction between different hypothetical periods of infectivity and susceptibility has been developed by one of us (Pike, 1967), but it will be some time before it can be tested adequately.

Summary

The hypothesis that cases of childhood leukaemia occur grouped together in space and in time has been tested by examining the distribution of the disease in Greater London.

Altogether 618 children were certified as having died of leukaemia under 15 years of age in Greater London during the period 1952–61. For each of these children the hospital records were sought and the clinical and haematological details reviewed. Four hundred and eighty-three children were accepted as having developed leukaemia under 10 years of age while resident in Greater London, and for these children information was obtained about the date and place of birth, the parents' place of residence at the child's birth, and the date and place of residence of the child at the onset of the disease.

The incidence of leukaemia varied between the 31 boroughs of the new Greater London Council, but the amount of variation (from 1.7 to 7.7 per 100,000 children per year) could easily be accounted for by chance variation of small numbers.

No evidence was found to suggest that the disease had been unusually common in any one year, or to suggest that it occurred more commonly at any one season, nor was there any evidence of temporal variation in the incidence of any of the principal subgroups of the disease (lymphoblastic and myeloblastic leukaemia and leukaemia occurring before or after the sixth birthday).

Evidence of clustering in space and time taken together was sought by examining whether pairs of cases that occurred close together in space also occurred close together in time. Thirteen subsets of the data were examined, and weak evidence of clustering was found for all cases of lymphoblastic leukaemia in regard to date and place of onset, and for cases of lymphoblastic leukaemia leading to death under 6 years of age in regard both to date and place of onset, and to date of birth and the place of the parents' residence at the child's birth.

The results obtained in relation to the onset of the disease are similar to but not identical with those reported previously by others, and provide some weak support for the general hypothesis under examination.

We are grateful to the Leukaemia Research Fund and the Medical Research Council for grants to one of us (R. M. H.) for the purpose of this study; to Mrs. Ranjana Ash and Mrs. Jean Bridger for locating the map references of the addresses and tracing the case records; to Mrs. Anna Frackiewicz (M.R.C. Clinical Effects of Radiation Research Unit) for extracting copies of the death entries of children in Greater London who died of leukaemia; to Mrs. Serina Bell for assistance in the computer programming; to Dr. Alice Stewart for allowing us access to her records; and to our colleagues in many London hospitals for their willing co-operation in making their case records available.

Leukaemia in Lewisham (1957-63)

S. P. LOCK,* M.A., M.B., M.R.C.P.; MAXINE MERRINGTON,† B.SC.

Brit. med. J., 1967, 3, 759–760

Several workers have reported that cases of leukaemia occur in clusters in place and time—for example, Kellett (1937), Heath and Hasterlick (1963), Knox (1964), Meighan and Knox (1965), and Mainwaring (1966). Conversely, it has also been reported that the disease does not occur in clusters (Clemmesen *et al.*, 1952; Ederer *et al.*, 1964; Barton *et al.*, 1965; Ager *et al.*, 1965; Lundin *et al.*, 1966). Until recently there have been no adequate statistical tests for detecting clustering; furthermore, the records of victims of leukaemia have not usually been available for the application of such statistical tests.

We here report our analysis of the incidence of leukaemia in a particular area—the former London borough of Lewisham—with special reference to the question of clustering. We have confidence that these records are largely complete and would expect to be able with these data to detect clustering if it occurred.

Materials and Methods

The patients studied had been diagnosed between 1 January 1957 and 30 December 1963 as having any type of leukaemia. At the time of diagnosis they were living in the London borough of Lewisham. Their names were obtained in a variety of ways: from case notes, with necropsy records from all the local hospitals, including Lewisham General Hospital, which provides a district haematological service for the area; from records of the South Metropolitan Cancer Registry, which are derived from the notifications from individual hospitals; and from the death certificates of all patients in the borough dying from leukaemia, kindly made available by Dr. W. M. Court Brown, of the Medical Research Council Clinical Effects of Radiation Research Unit in Edinburgh. The case notes of all the patients were obtained from the hospitals concerned.

In all, 115 patients were diagnosed as suffering from leukaemia; their ages ranged from 2 to 89 years. The clinical types were distributed as follows: 37 acute myeloid, 18 acute lymphatic, 4 myelomonoblastic, 21 chronic myeloid, 32 chronic lymphatic, and 3 erythroleukaemia. In almost every instance the diagnosis had been made from conventional haematological examinations, but one case of chronic lymphatic leukaemia had been diagnosed only at necropsy. The date of the first symptom, the date of diagnosis, and the date of death were all recorded. The addresses of the patients when they developed leukaemia were obtained. The location of each individual address was accurately determined by visiting it.

Statistical Analysis

Several statistical techniques are now available for determining whether a group of patients who develop a particular disease at about the same time also live near each other.

Two methods have been applied to the 115 cases of leukaemia in Lewisham. The first (David and Barton, 1966) is worked out on the basis of testing whether the spatial pattern is random within a group of cases in time. Initially all the cases are written down chronologically. They are then divided into groups in time according to a rule, which must be decided on before the statistical analysis is calculated. Unless there is some particular reason for choosing a special interval it is usual to choose the groups with several different time intervals between them and to repeat the same statistical analysis for each interval. The next step is to find the distances between all cases. This may be done by taking the map readings of each patient's address from the National grid; with these as co-ordinates the distances are calculated. The David and Barton statistical test is the ratio of the variation within time groups to the variation of all the possible distances between the cases. If the cases are randomly distributed this ratio will be unity; the closer they are to each other within a time group the smaller the ratio will be. As a yardstick for deciding whether clustering exists we may subtract unity from this ratio and divide by the standard deviation. This is the David and Barton test criterion. If this measure is less than -2 it can be concluded that there is some clustering effect. The method of calculating the ratio and its standard deviation has been published (Barton *et al.*, 1965; David and Barton, 1966).

This test was calculated for each group of patients suffering from the different clinical types of leukaemia; it was also calculated for all 115 cases combined together. It was applied by using various time intervals between groups of patients. Finally, the patients were divided into adults and children (under 15 years old), and again the test was calculated. In none of these tests was the difference between the ratio and unity even as much as one and a half standard deviations. Therefore it must be concluded that among the cases of leukaemia in Lewisham during 1957 to 1963 there was no evidence of any clustering effect.

The second method used for detecting clustering is that devised by Knox (1964). All the cases are considered in pairs; their distance apart is calculated and their time apart is noted. If the number of cases with a short distance and a short time apart is larger than would be expected if they were randomly distributed then clustering must occur. Whatever specific distances and times were chosen for the test, there were no excessive numbers of pairs of cases close to each other in place and time. Thus this statistical test also provided no evidence of clustering.

Discussion

The difficulty with all statistical tests for space–time clustering is that the definition of what is "close" in time and what is "close" in distance will vary enormously. The results given by Knox (1964) for childhood leukaemia in Northumberland and Durham show that pairs of cases occurring within 60 days and within 1 km. of each other were unduly frequent. The conclusions reached by Meighan and Knox (1965) for childhood leukaemia in Portland, Oregon, showed that an excessive number of pairs of cases were closer than 250 days apart and closer than 4 km. apart. The results for acute leukaemia in childhood in the Liverpool area given by Mainwaring (1966) show an excessive number of pairs with short distances and short times apart, the highest levels of significance being for

---

† Department of Statistics, University College, London W.C.1.

pairs of cases with intervals less than 300 days and 4 km. Other investigators have drawn conclusions based on personal observations rather than on the results of any statistical tests. For example, Heath and Hasterlick (1963) reported eight cases of leukaemia among children living in Niles, Illinois, between 1957 and 1960. This was at a time when the population was expanding sharply (in 1950 the population was about 3,500 and in 1960 about 20,000). Wood (1960), describing leukaemia in Cornwall over a 12-year period, stated that there was a tendency to find tiny foci of victims living in close proximity but there was no significant predominance in any particular district. Dowsett (1966) reported similarly of cases in Kingston, Surrey. Heath and Manning (1964) described 14 cases in four communities in the United States.

The statistical test put forward by David and Barton (1966) has the advantage that it picks out non-randomness without the need for defining a " close " distance. The criterion is based on the overall average of all possible distances between all cases. A definition of shortness in time must be made. This test was carried out (Barton *et al.*, 1965) on cases of acute leukaemia in Northumberland and Durham, Liverpool, Birmingham, Bristol, Sheffield, and Cornwall. The results gave no evidence for the presence of clustering. Both this test and Knox's test were used by Pike *et al.* (1967) in analysing the incidence of Burkitt's tumour in the West Nile district of Uganda; both tests demonstrated significant space–time clustering.

In an investigation in Connecticut, Ederer *et al.* (1964, 1965), using a different statistical technique, analysed over 300 cases of leukaemia in children between 1945 and 1959 and found no evidence of " calendar-year clustering within towns," though, using their statistical technique, they did find evidence for clustering of poliomyelitis and hepatitis.

The 115 cases studied in Lewisham included several different clinical types of leukaemia (cytological and clinical), and the numbers of any one type were small. The data indicate that there is no evidence of clustering of leukaemia taken as a whole, nor do they provide evidence of clustering of one or other specific subtypes of leukaemia. It would appear that if cases of leukaemia are clustered at all the degrees of clustering must be very slight, and quite unlike that found in poliomyelitis and infectious hepatitis.

Summary

Two statistical criteria for testing the association of cases of leukaemia in place and time were calculated for 115 patients in the London borough of Lewisham between 1957 and 1963. The analysis gives no evidence for any clustering of these cases.

We wish to acknowledge with thanks the help given by many doctors and medical records officers in hospitals in South-east London and elsewhere. Mr. P. M. Payne, Director of the South Metropolitan Cancer Registry, kindly gave us details of his registered cases of leukaemia in the district.

The calculations were carried out on the I.C.T. Atlas Computer at the University of London Institute of Computer Science. We wish to acknowledge gratefully the expert assistance given us by Mrs. Pat Hills, Miss Norma Pateman, and Miss Pat Williamott, of University College, London, in processing these data. Dr. Malcolm Pike, of the M.R.C. Statistical Research Unit at University College Hospital Medical School, London, kindly helped us concerning the calculations with the Knox test.

Transit Times of Food in Patients with Diverticulosis or Irritable Colon Syndrome and Normal Subjects

O. N. MANOUSOS,* M.B., D.PHIL.; S. C. TRUELOVE,* M.D., F.R.C.P.; K. LUMSDEN,† M.B., B.CHIR., D.M.R.E.

Brit. med. J., 1967, **3**, 760–762

The rate of passage of food residue through the alimentary canal of normal human subjects has been studied extensively, but there are no relevant data with regard to patients with diverticula of the colon.

Hurst (Hertz) (1907) administered bismuth carbonate mixed with food to normal subjects and followed the progress of the food residue by means of radiographs; he found that a proportion of the radio-opaque material was still in the large bowel three days after its administration. Alvarez and Freedlander (1924) studied the transit times by means of small glass beads taken with food and found that only 70% of the beads had been passed by the third day. Similar results were obtained by Burnett (1923), who used millet seeds as the tracer substance. Todd (1930) and Lönnerblad (1951) studied the transit time of the small intestine by using barium sulphate mixed with water, but, as Cole (1914) suggested, unless the tracer substance is mixed with an ordinary meal the results are not representative of the actual progress of food residues through the gastrointestinal canal.

The figures of transit times given by Hurst (1919) for the normal are generally accepted (Barclay, 1933; Feldman, 1948). The food reaches the caecum in three to four hours, the hepatic flexure in six hours, the splenic flexure in 10 hours; between 18 and 24 hours the sigmoid is filled and some of the contents have been expelled; but, as was pointed out by Hurst himself, there is a wide variation in the normal transit. Indigestible material (roughage) increases the speed of food residue through the digestive tract, as has been shown by the comparative studies of McCance *et al.* (1953). They studied radiologically the transit time of white and brown bread administered with a small amount of barium sulphate to normal subjects. It was found that the residue from the brown bread left the colon 24 hours sooner than that from the white bread.

* Nuffield Department of Clinical Medicine, the Radcliffe Infirmary, Oxford.
† Consultant Radiologist, United Oxford Hospitals, Oxford.

Present Study

The transit time of food through the digestive tract was studied in 43 patients with diverticulosis (20 males and 23 females ; mean age 68 years), 75 patients with the irritable colon syndrome (40 males and 35 females ; mean age 42 years), and 88 normal subjects (42 males and 46 females ; mean age 59 years).

A minority of the patients with diverticulosis and some of the patients with the irritable colon syndrome were on treatment with anticholinergic drugs because of chronic intermittent symptoms ; the medication in these patients was stopped at least two days before the period of observation started.

Methods.—The subjects studied were instructed to drink 30 ml. of a preparation of barium sulphate (Fotogel or Micropaque) with each of their four main meals in one day. The next morning a radiograph of the abdomen was taken, and this was repeated on each successive morning (up to a maximum of six) until the radio-opaque material had virtually disappeared. (This procedure has also been used in order to obtain information regarding the incidence of diverticulosis in the general population (Manousos *et al.*, 1967b).) Two factors were examined: (1) the head of the barium column indicating the progress of food eaten 24 hours previously, and (2) the number of days that the barium—that is, the food—took to disappear from the gastrointestinal tract.

Results

As shown in Table I, the head of the barium column 24 hours after administration of barium with food was above the sigmoid colon in more than 27% of the normal subjects, whereas the proportions of patients with diverticulosis and the irritable colon syndrome were 9.3% and 5.3% respectively. Table II shows that the difference in transit of food residue between normals and patients with diverticulosis is statistically significant.

When the number of days required for the radio-opaque material to leave the colon is taken as a measure of the progress of food residue through the alimentary canal it is found that five or more days are required by 33% of the normal subjects, 23.3% of the patients with diverticulosis, and 18.1% of the patients with the irritable colon syndrome (Table III). Again the difference between normals and patients with diverticulosis is statistically significant (Table IV).

Discussion

Constipation has been thought to be a factor of aetiological significance in the development of diverticula by many investigators (Fischer, 1900 ; Beer, 1904 ; Turell, 1959 ; De La Vega *et al.*, 1964), and according to Jordan (1926) diverticulosis is a special manifestation of chronic intestinal stasis. The term "constipation" often has a vague meaning (Johnson, 1943), but when constipation is defined as "undue delay of passage of stool and, therefore, the difficult expulsion of hard dry matter," then the incidence of constipation in diverticular disease is only 14% (Horner, 1958).

Barclay (1933) pointed out that the statements of patients about constipation are often proved to be unreliable when they are examined radiologically.

The present study of the transit times shows that intestinal stasis is not present in patients with diverticulosis. On the contrary the progress of food through the gastrointestinal canal is significantly faster in patients with diverticulosis than in normal controls.

The similarity of the pattern of transit times between patients with diverticulosis and those with the irritable colon syndrome is of interest. The chronic intermittent symptoms of the two conditions are identical, and Bockus (1964), who made repeated radiological examinations in patients with the irritable colon syndrome, found that a proportion of them develop diverticula some years after the diagnosis of irritable colon, and pointed out that colonic irritability may be a predisposing factor in the development of diverticula.

Pathological studies (Keith, 1910 ; Edwards, 1939 ; Morson, 1963 ; Williams, 1963) suggest that diverticulosis may be the result of incoordinated activity of the colonic musculature. The function of the colon in patients with diverticulosis has not been studied extensively. Painter and Truelove (1964) found that injection of morphine produced high pressures inside segments of the colon bearing diverticula. They suggested that in diverticulosis the colon may show exaggerated responses to normal stimuli—for example, food or drink. The effect of eating a meal on the motility of the sigmoid colon of patients with diverticulosis has been studied (Manousos *et al.*, 1967a). The results indicate that the effect is greater than that observed in normal subjects, and, again, a similarity was observed between the response of the colon in patients with diverticula and patients with the irritable colon.

As shown by the study of the transit times and the review of the literature, there are many points in common between colonic diverticulosis and the disorders of colonic motor activity covered by the term "irritable colon syndrome." It appears likely that in both conditions the underlying mechanism is a functional disorder of the colonic musculature. The fact that many cases of colonic diverticulosis are quite symptomless seems to contradict this idea, unless we accept the view put forward by Williams (1963) that incoordinated muscular activity of the colon may be present without causing any symptoms.

Summary

The transit times of food residues through the gastrointestinal tract have been studied by administering food mixed with a small amount of barium sulphate. Observations were made on 88 normal subjects, 75 patients with the irritable colon syndrome, and 43 patients with diverticulosis. The transit times were found to be substantially shorter in the patients with diverticula than in normal subjects and to follow closely the transit shown by patients with the irritable colon syndrome. This finding is put forward as evidence supporting the hypothesis that incoordinated colonic activity is the basic abnormality in diverticulosis.

We wish to express our gratitude to all the patients and normal subjects who volunteered to take part in this study, the radiographers of the United Oxford Hospitals for their help, and the Medical Research Council for financial support.

Prevalence of Colonic Diverticulosis in General Population of Oxford Area

O. N. MANOUSOS,* M.B., D.PHIL.; S. C. TRUELOVE,* M.D., F.R.C.P.; K. LUMSDEN,† M.B., B.CHIR., D.M.R.E.

Brit. med. J., 1967, **3**, 762–763

It has been generally accepted that diverticulosis of the colon is a common condition in Western countries, especially in the older age groups (Barborka, 1958; Reichman and Watkins, 1962). However, up to the present time the frequency of diverticulosis has been calculated from radiological studies carried out on patients or from post-mortem examinations in hospital, and consequently the results apply only to selected sections of the population. Spriggs and Marxer (1925) examined 1,000 consecutive barium enemas and found diverticula in 10%. Rankin and Brown (1930) studied 24,620 barium enemas and found diverticula in 5.7%. They reported a similar prevalence of diverticulosis (5.2%) in 1,925 necropsies. All except one of the necropsies were carried out on subjects older than 40 years.

Pemberton *et al.* (1947) reviewed a large number of radiographs of the colon and found diverticula in 8.5%. Welch *et al.* (1953) examined 2,000 barium enemas and found diverticula in 20% of the patients over the age of 60.

Until some years ago diverticula were more common in men than in women (Spriggs and Marxer, 1925; Ochsner and Bargen, 1935); recently, however, it appears that a change in sex ratio is taking place and a female preponderance is now commonly observed (Ford, 1953; Brown and Toomey, 1960). Table I shows the sex ratio in diverticulosis and diverticulitis reported by various authors. In a recent study on the prognosis of diverticulosis and diverticulitis (Manousos and Truelove, 1967) it was found that whereas below the age of 60 diverticula were equally common in men and women, above that age the condition was much more common in women. It was also shown that the number of patients admitted to hospital with diverticulosis, diverticulitis, and the complications of diverticular disease is increasing, and this probably indicates a true increase in the prevalence of the disease as a whole.

In view of the lack of accurate information on the frequency of diverticulosis in the population at large the present study was made.

* Diverticulitis and its complications. † Diverticulosis.

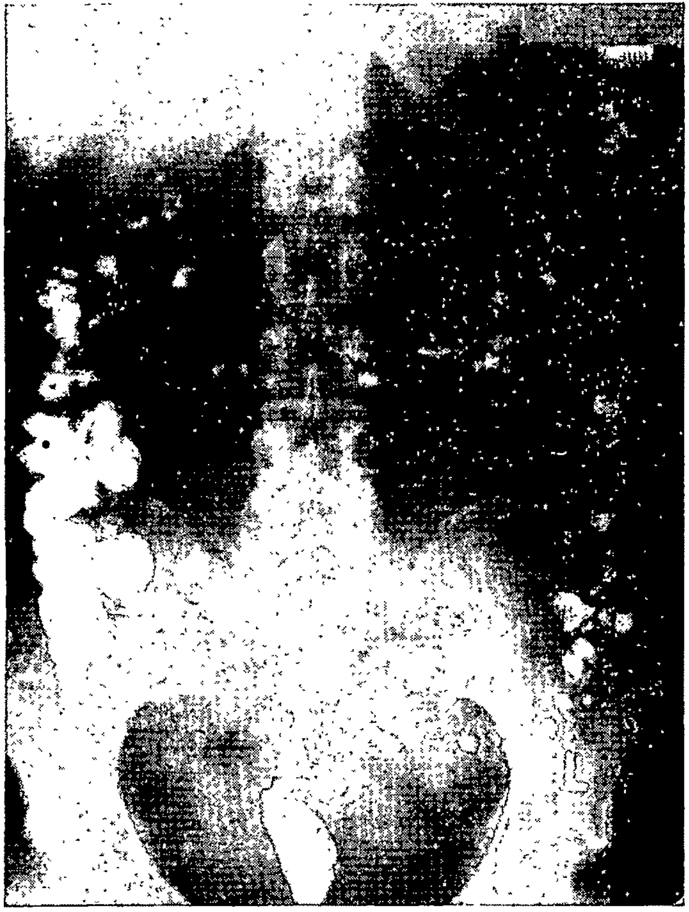
Methods and Subjects

The radiological appearances of the colon of 109 subjects without gastrointestinal symptoms were studied. The majority of the subjects were healthy volunteers who were either members of the staff of the Radcliffe Infirmary or visitors to inpatients. A minority of the subjects were patients in a geriatric unit (Cowley Road Hospital, Oxford) who were volunteers and who were completely free from gastrointestinal symptoms.

---

* Nuffield Department of Clinical Medicine, the Radcliffe Infirmary, Oxford.
† Consultant Radiologist, United Oxford Hospitals, Oxford.

The subjects studied were instructed to drink a small quantity of radio-opaque material (30 ml. of Micropaque or Fotogel) with each of their four main meals on one day. The next morning a radiograph of the abdomen was taken, and this was repeated on successive mornings (up to a maximum of six) until the radio-opaque material had virtually disappeared. The degree of accuracy of the method in demonstrating colonic diverticula (see Fig.) was tested on 20 known cases of diverticulosis in which the diverticula had been shown by barium enema. The follow-through method revealed the diverticula in every case.



Radiograph showing extensive diverticulosis of colon revealed by barium follow-through technique described in text.

It is interesting that in the first recorded case of colonic diverticula in which the diagnosis was made radiologically (Abbé, 1914) the diverticula were shown by follow-through examination whereas the radio-opaque enema had failed to demonstrate them.

By the follow-through method employed in the present study it was possible to obtain an estimate of the prevalence of diverticulosis. The method was also used as a measure of the transit times of food (Manousos, Truelove, and Lumsden, 1967).

Results

The radiographs were examined carefully, and only when the appearances were unequivocal were the diverticula accepted. The results (Table II) indicate that diverticulosis of the colon is slightly commoner in women than in men in the population studied. No cases of diverticulosis were found below the age of 40, but the prevalence of the condition increases steadily with age and reaches a peak above the age of 80 years. Above the age of 60 the condition was present in 15 out of 43 subjects (34.9%); below the age of 60 it was present in 5 out of 66 subjects (7.6%).

TABLE II.—*Prevalence of Diverticulosis in the Various Age Groups*

Age	Men			Women			Both Sexes		
	No. of Subjects	With Diverticula		No. of Subjects	With Diverticula		No. of Subjects	With Diverticula	
		No.	%		No.	%		No.	%
< 40	14	0	0·0	25	0	0·0	39	0	0·0
40–59	14	2	14·3	13	3	23·1	27	5	18·5
60–79	10	3	30·0	14	4	28·6	24	7	29·2
80+	10	3	30·0	9	5	55·5	19	8	42·1

Discussion

One of the best studies of the frequency of diverticulosis of of the colon is that of Debray *et al.* (1961), which was carried out in France. They studied the radiographs of 500 barium enemas taken at random from a much bigger number carried out in hospital or by their colleagues. They found a low frequency of diverticulosis in patients under the age of 40, but thereafter the frequency rose with each successive age group until it reached 40% over the age of 70 years. The weakness of their study is that many of the patients had gastrointestinal symptoms and therefore they cannot be regarded as an unbiased sample of the general population. The present study, though dealing with comparatively small numbers, has been concerned with subjects completely free from gastrointestinal symptoms, and therefore its results may be a closer reflection of the prevalence of diverticulosis of the colon in the general population.

Summary

An estimate of the prevalence of diverticulosis of the colon in the Oxford area has been obtained by studying healthy volunteers. A follow-through radiological method was used. Diverticulosis was found to be present in one in every three persons above the age of 60 years. Below that age the condition was present in 7.6% of the population studied. Diverticula were more common in women than in men. A review of the literature shows that a female preponderance in diverticulosis has been constantly observed during recent years.

We are grateful to the volunteers who took part in this study. We also wish to thank Dr. L. Z. Cosin and his staff for allowing us to study patients under their care, the radiographers of the United Oxford Hospitals for taking the radiographs, and the Medical Research Council for financial support.

Electric Fire Burn

ANDREW GUNN,* M.A., M.B., B.CHIR., F.R.C.S.

Brit. med. J., 1967, 3, 764–766

Electric fires are of three types: silica-sheathed, fireclay-mounted, and exposed rod. Children who grasp the heating element of electric fires of the exposed-rod type sustain severe burns of the hand. Wynn Williams (1955) reviewed 100 cases of children with burnt hands and noted that 36% were due to electric fires. Muir (1958) described and illustrated the electric bar fire burn of the hand, separating it from electric current burns and defining it as a thermal injury. Clarkson and Pelly (1962) also described it as a severe and specific injury of the hand in children. Evans (1962) recorded the impression that the injury was happening more often. This paper reviews the incidence and results of this burn and discusses prevention.

Incidence

From 8 February 1953 until 31 December 1966 the Children's Burns Unit at Guy's Hospital admitted 735 children for burns of all kinds. Of these, 19 were admitted with an electric bar fire burn of the hand. Since 1962 four additional children have been treated for flexion contracture due to the same cause after the burn had healed elsewhere.

The annual incidence of fresh burns is given in Table I; there appear to have been slightly more cases in recent years. The burns occur chiefly in winter, as do other burns (Clarkson, 1965); but children have been admitted in every month of the year.

TABLE I.—*Electric Fire Burn of Hand. Admissions to Children's Burns Unit: Annual Incidence*

	1953	54	55	56	57	58	59	60	61	62	63	64	65	66
No.	0	3	0	0	1	2	2	0	1	1	2	3	2	2

According to Clarkson (1965) 60% of the children were admitted for burns of all types from addresses in S.E. London and 20% from S.W. London postal districts. Twelve out of 19 children with an electric bar fire burn were admitted from S.E. or S.W. London.

The age and sex incidence of this injury is shown in Table II. A few more boys than girls are seen to be involved, but the predominance of male toddlers is noted. All these 19 children who were admitted up to 31 December 1966 were white; no immigrants have been admitted with this burn.

TABLE II.—*Electric Fire Burn of Hand. Age and Sex Incidence*

Sex	Age in Years												Total
	0–1	1	2	3	4	5	6	7	8	9	10	11	
M	0	2	8	0	0	0	0	0	1	0	0	0	11
F	0	1	1	1	1	1	1	0	0	1	0	1	8

Mode of Accident

The hospital notes are not always complete and the description of injury is not always full. However, it has been possible to trace some more recent patients, and their mothers have answered a questionary. From their answers and the case notes the following facts emerge.

(1) The accident may happen very quickly, even if adults are present in the room. Usually children are in the room alone or with other children.

(2) A small child can easily slip his hand through the guard or over or under it. The British Standard Specification (British Standard 1945) is not designed to prevent this happening, and a note of this is made in the text. The guard is designed to prevent severe clothing burns, and indeed the incidence of clothing burns in Birmingham has fallen since its adoption (Bull, Jackson, and Walton, 1964).

(3) A severe burn may be sustained even if the fire is grasped after being switched off or while the fire is warming up. When the fire first glows dull red the surface temperature of the nickel-chrome wire element is 550° C. At normal working temperatures the element glows a bright orange-yellow, and then the surface temperature is 800–850° C. (Belling, 1966).

(4) After grasping the element a small child may easily sustain a burn of the whole of the volar surface of one or both hands (Fig. 1). Only one infant had all the finger-tips of one hand burnt. If there are two or more elements in one fire then a child may burn the dorsum of the finger or hand on the second element (Fig. 2).

(5) It may be difficult to release a child who has grasped the fire. The burnt flesh of the hand may stick to the element. The closed hand may be trapped between the bars of the guard. An electrical effect causing muscle spasm may make it more difficult to release the child.

Treatment

None of the children admitted to the Guy's Children's Burns Unit after an electric fire burn have died, and burns have been confined to the part of the hand in contact with the heating element. The results are given in Table III and compared with the results of other burns. Though it is not the purpose of this paper to deal with treatment the results cannot be assessed without reference to it.

TABLE III.—*Results in 116 Children with Burns of the Hand*

Type	No. of Cases	No. whose Hand Grafted	Amputation	Late Surgery
Electric-fire burn ..	19	17	2	7
Electric-current burn:				
Low-voltage:				
Flash	5	0	0	0
Contact	10	8	0	0
High-voltage:				
T.V. set	2	2	1 finger	0
Conductor rail ..	2	2	2 major upper limb	0
Non-electric causes ..	78	9	1 finger	0

The following local measures are employed in electric fire burns after sedation (Gunn, 1967).

Toilet.—The whole upper limb is thoroughly cleaned with Savlon.

Extension Splintage.—In previous papers Wynn Williams (1955) and Clarkson and Pelly (1962) have stressed the importance of extension splintage. There are many advantages in treating superficial burns of the hand by exposure. Potentially deep burns of the palm or the volar surface of the fingers in children should be treated by extension splintage in order to prevent flexion contracture of the fingers. Flexion contracture can be prevented by splintage, but may develop within days without splintage. An established contracture may require prolonged treatment. In these children joint stiffness has not been seen even after prolonged extension splintage of the wrist and fingers.

---

* Children's Burns Unit, Guy's Hospital, London S.E.1.

Skin-grafting.—Deep burns require skin-grafting. In practice, burns which are unhealed after 14 days are regarded as deep. It is an advantage to delay grafting until the third week after burning for the following reasons. The diagnosis of depth is easier and unnecessary excision is avoided. The slough is more readily separated and haemorrhage is less, so that excision and grafting can be completed in one operation. Where the graft bed persistently bleeds grafting may be delayed for two to five days while the hand is dressed with polyurethane foam sponge. Discharges are readily absorbed and a clean granulating surface is left, which is ideal for grafting. As a rule thick split-skin grafts cut from the thigh give a reliable take and satisfactory permanent cover. If tendons, bones, or joints are exposed then flap cover is indicated.

In only two patients were the burns superficial, and these did not undergo skin-grafting. The remaining 17 required skin-grafting to heal. Of these 17, six developed flexion contractures of the fingers (Fig. 3) or adduction contracture of the thumb (Fig. 4) and required further surgical treatment. One patient underwent primary amputation of the ring finger (Fig. 5); another not only required primary amputation of the little finger but also developed a flexion contracture later.

On average these children were in hospital for 34.7 days. This figure does not take into account the fact that not all children were admitted on the day of burning. Nor does it allow for the fact that a few children had their hospital stay interrupted for some reason or other. The five-week average stay suggested that the time required for primary healing is likely to be five or six weeks. This agrees with the 6.5 weeks' hospitalization given by Wynn Williams (1955) for deep burns treated surgically.

Treatment of established contractures is apt to be protracted. Several operations may be required to correct all deformities

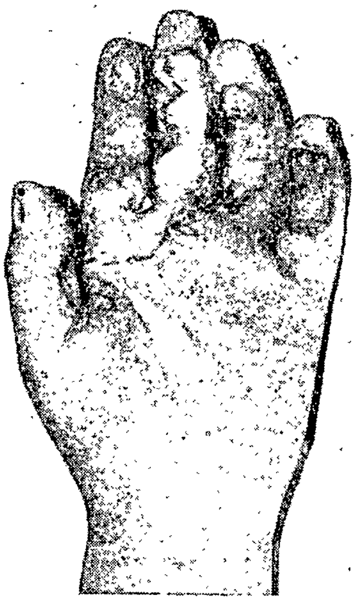

FIG. 1

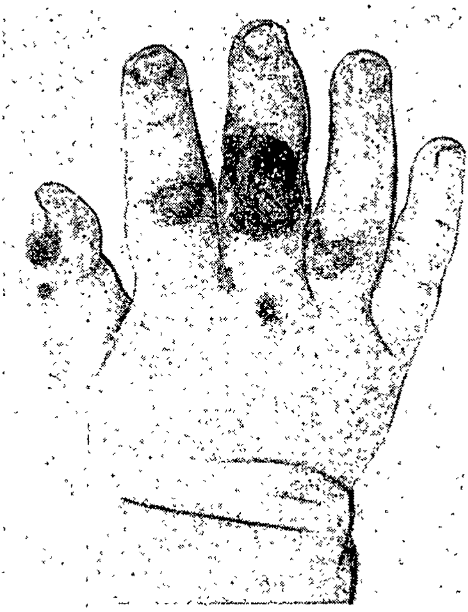

FIG. 2

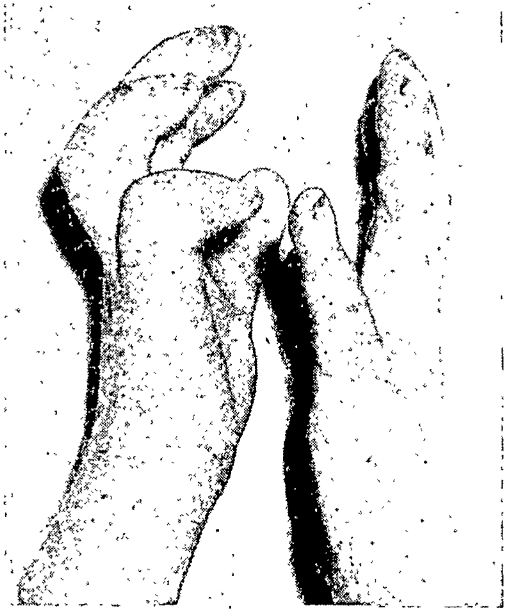

FIG. 3

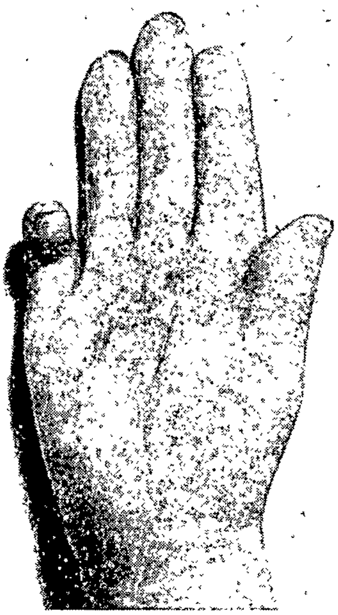

FIG. 4

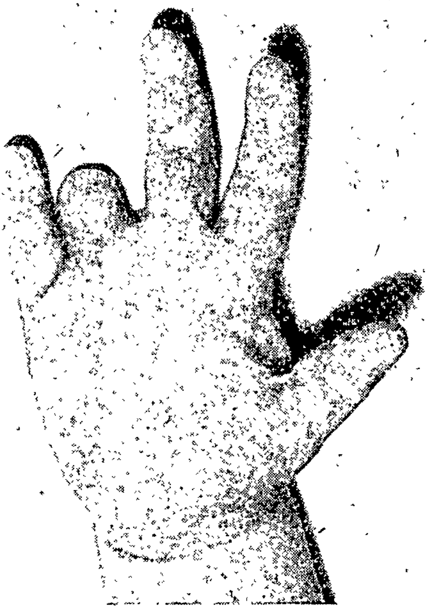

FIG. 5

FIG. 1.—Recent burn of the fingers. Lesions may be more extensive than this.

FIG. 2.—Dorsum of the middle finger shows a full-thickness burn requiring flap cover.

FIG. 3.—Severe flexion contractures of right little and ring fingers after healing; left ring finger and right middle finger are affected to a lesser degree.

FIG. 4.—This burn healed with adduction contracture of the thumb and severe flexion contracture of the little finger.

FIG. 5.—The right ring finger was so badly damaged that amputation was unavoidable.

when many fingers are scarred. Recurrence after correction is also a serious problem.

Results

The results show that the electric fire burn is potentially very serious because the element is very hot and a large area is burnt in a small hand. Comparison with other types of burn will also show that this is the most important burn of the hand in children. Most electric current contact burns of children occur at the normal domestic voltages and produce small burns which usually heal without complications after grafting. Low-voltage flash burns have all been superficial. High-voltage burns may be disastrous, but they seldom occur. Patients with a wide variety of non-electric burns have been admitted; the majority of them had extensive or potentially deep burns elsewhere and only a small number required skin-grafting to the hand.

It is therefore made clear that if a child grasps the heating element of an electric fire of the exposed rod type he will sustain a severe and potentially crippling injury. The incidence throughout the country remains uncertain. It may be that more or fewer cases than average are admitted to the Children's Burns Unit at Guy's Hospital. But it has been estimated that the Guy's Children's Burns Unit serves a population of 2,500,000 (Clarkson, 1965), and in recent years two to three new cases of electric fire burns have been admitted annually. The Guy's figures may not be representative; but if they are then 40 to 60 new cases may occur each year.

There are good reasons for believing that the risk is increasing. Figures supplied by the Electricity Council show that domestic consumption has increased. Estimates show that more people own electric space heaters and that more electricity is used by these heaters (Table IV).

TABLE IV.—*Electricity Statistics—England and Wales*

	1954–5	1965–6
Domestic consumption (million kWh) ..	17,017	50,829
Ownership of domestic consumers of electric space heater:		
% consumer owning	60·5	79·7
No. of consumers	7,275,000	12,156,000
Loading (MW)	17,000	41,875
Use of electricity space heating (million kWh)	4,000	12,500

Prevention

For the above reasons it is desirable to review measures which might prevent these accidents. (1) Doctors should know about these accidents and how serious they may be. In turn, they could warn the public and ensure that the victims got prompt and adequate treatment. (2) If these accidents were all notified the necessity for further prophylactic measures could be assessed. (3) The safety of electric space heaters and the design of their guards might be reviewed. It would be relatively easy to set a new British Standard for fireguards. It does not seem likely that cost would be prohibitive, but a new guard might greatly reduce the effectiveness of the space heater. (4) It is desirable for all electric space heaters to be in a clear space and protected by a guard, just as open fires and paraffin stoves should be. (5) If a suitable guard cannot be designed for electric space heaters of the exposed rod type, then it might be better to abandon them in favour of fireclay-mounted or silica-sheathed electric space heaters. Silica-sheathed electric space heaters are regarded as safest by the Consumers' Association (*Which?*, 1965).

Summary

The elements of electric fires of the exposed rod type are sometimes grasped by young children. The child sustains a thermal injury of the palm of the hand which is almost always deep and is potentially crippling: 89% require grafting, 10% lose a finger, and 37% need surgery for late complications. Late complications may require protracted treatment.

The electric fire burn is the most important burn of the hand in children. It is estimated that 40 to 60 may occur in Great Britain annually. As the use of electric fires increases so may the risk of this accident.

To reduce the incidence the following measures are suggested: the risk must be publicized; cases should be made notifiable; the design of the guards on these fires should be reviewed; electric fires must be enclosed by a guard; and electric fires of the exposed rod type may have to be discarded in favour of safer models.

I wish to thank Mr. P. W. Clarkson for kindly allowing me to study his patients, and for his constant encouragement in the preparation of this paper. The Electricity Council kindly supplied me with figures relating to the domestic consumption of electricity and the domestic use of electric space heaters, and allowed me to publish them. I am grateful to Mr. J. Rytina, of the Department of Medical Illustration, Guy's Hospital, for photographs illustrating this paper.

Effects of a "New" Human Respiratory Virus in Volunteers

A. F. BRADBURNE,* B.SC.; M. L. BYNOE,* M.B., D.T.M.&H., D.OBST.R.C.O.G.
D. A. J. TYRRELL,* M.D., F.R.C.P., M.C.PATH.

Brit. med. J., 1967, 3, 767–769

We recently reported the cultivation in organ cultures of a virus, B814, which caused colds in volunteers but could not be detected or propagated in tissue cultures (Tyrrell and Bynoe, 1965). Hamre and Procknow (1966) have discovered a "new" virus in the respiratory tract of six students suffering from colds. There was a slight viral cytopathic effect in tissue cultures of human embryo kidney cells, but the virus was subsequently adapted to the WI-38 strain of human embryo fibroblasts. Both of these viruses were ether-labile but apparently unrelated serologically to any known myxoviruses. It now appears that they are morphologically identical and indistinguishable from the viruses of avian infectious bronchitis (Almeida and Tyrrell, 1967), and mouse hepatitis (Tyrrell and Almeida, 1967). The particles are 80–120 mμ in diameter, pleomorphic, and surrounded by a fringe of club-shaped projections about 20 mμ in length. Recently, further viruses of this morphological type have been isolated in organ cultures by McIntosh *et al.* (1967).

We have now given the prototype strain, 229-E, of Hamre and Procknow to volunteers in order to determine whether it causes colds and to study serum neutralizing antibody during infections with viruses of this type.

Materials and Methods

Virus.—The 229-E virus was received from Dr. Hamre as tissue culture fluid. It was then passed in human embryonic lung fibroblasts and in organ cultures of human embryo trachea. This material was not apparently contaminated with bacteria or other viruses and was inoculated into volunteers, in whom it was passed further. For the inoculation of volunteers organ culture fluids or nasal washings were diluted 1 in 10 in saline and 0.5 ml. was dropped into each nostril.

Tissue Cultures.—Locally propagated strains of human embryo lung fibroblasts were used. They were cultivated by the methods of Hayflick and Moorhead (1961) and maintained in a roller drum at 33° C. in a medium containing 2% ox serum and 98% Eagle's medium (Gibco: G13) with penicillin, streptomycin, and achromycin.

Organ Cultures.—These were maintained by a modification (Tyrrell and Blamire, 1967) of the original method of Hoorn (1966) with 1.25 ml. of Eagle's medium containing 0.2% bovine plasma albumin in an atmosphere of 5% CO_2 in air, at 33° C.

Virus Isolation.—Nasal washings were collected with about 10 ml. of sterile saline, mixed with an equal volume of nutrient broth, and stored at $-70°$ C. Two or three cultures of fibroblasts were inoculated with 0.2 ml. of nasal washings and changed six hours later. A widespread cytopathic effect appeared within four days of inoculation in the case of positive isolation. All isolated viruses were identified by neutralization with a specific antiserum produced in guinea-pigs and provided by Dr. Hamre.

Neutralization Tests.—Serial dilutions of inactivated serum were mixed with equal volumes of virus, held at room temperature for two hours, and 0.2 ml. of the mixture was inoculated into each of two or three cultures. The test was read about six days later. Complete neutralization of the virus was taken as the end-point. It was found essential to use small doses of virus in order to detect antibody, and in tests reported here between 25 and 100 TCD$_{50}$ were employed. In the serological survey all sera were tested at a dilution of 1 in 10. A number of preparations of 229-E virus fixed complement with volunteers' sera. However, no rising titres were detected in the sera from infected volunteers; it is therefore not certain that the fixation was specific, and consequently the results are not reported here.

Volunteers.—These were of both sexes, aged 18 to 50 years, and were cared for in isolation as described elsewhere (Andrewes, 1948; Tyrrell, 1965).

Sera were collected before inoculation and two to three weeks later, and nasal washings were collected daily for five days after inoculation.

Results

As a preliminary to volunteer inoculation we wished to know whether specific antibodies against the virus 229-E were present in the sera of inhabitants of Britain. Accordingly sera collected over the past 10 years from subjects living in various areas were tested at a dilution of 1 in 10 in the neutralization test. As can be seen from Table I, about 30% of sera neutralized the virus.

TABLE I.—*Presence of Neutralizing Antibody in Human Sera*

Age Group (years)	No. of Sera		Percentage Positive
	Tested	Positive	
0–5	32	8	25
6–10	23	5	23
11–15	39	10	26
16–20	40	8	20
21–50	81	32	41
Total	215	63	29

The adult sera were collected from volunteers arriving at the Unit over the past 10 years. The minors' sera were taken from hospital patients in Liverpool and Sheffield.

About 40% of adults possessed antibody, and though the incidence was lower in children it seemed that they also were being infected by this or an antigenically related virus even within the first five years of life.

Passage of Virus in Volunteers

The passage history of the virus is summarized in Fig. 1. This shows that after a total of seven passages in tissue cultures in the U.S.A. and here it multiplied freely in human tracheal epithelium. However, the cilia continued to beat for eight days and sections of the cultures showed little abnormality. Organ culture fluid apparently produced a cold in four out of six volunteers. Nasal washings were collected from a volunteer who developed a cold and excreted virus, and these were passed to more volunteers. At each of a total of four serial passages in volunteers, colds were produced. Virus was recovered in tissue culture, and the dose of virus in the diluted nasal secretion used for each passage is shown on the left of the diagram.

---

* From the Common Cold Research Unit, Salisbury, Wilts.

Twenty volunteers were given saline in parallel with these experiments and none developed colds. There is therefore no doubt that the virus did multiply in the human respiratory tract and apparently caused colds.

FIG. 1.—Passage history of the 229-E virus.

Table II shows that half the inoculated volunteers developed colds; virus was recovered from all of these subjects but from only about one-third of those who remained well, and this difference is highly significant statistically. Nevertheless, the frequency of virus excretion varied a great deal from individual to individual, even when small doses of virus derived from man were given; this can be seen from Table III, the amount and period of virus excretion not apparently being related to the occurrence of colds. Only one volunteer excreted virus on the day after inoculation, and the frequency of virus excretion was at its peak at about the same time as the peak of clinical symptoms, as can be seen from Fig. 2. The titre of virus in 10 positive nasal washings ranged from $10^{0.5}$ to $10^{2.5}$ with a geometric mean of $10^{1.5}$.

TABLE II.—*Relation Between Virus Isolation and the Occurrence of Colds*

Type of Volunteer	Results of Virus Isolation Tests		
	Positive	Negative	Total
Inoculated { Colds	13	0	13
Inoculated { No colds	5	8	13
Uninoculated: No colds ..	0	6	6
Total	18	14	32

	Duration of Virus Excretion (days)			
	1	2	3	4
No. of volunteers who excreted virus for indicated number of days ..	3	1	4	4
No. of above volunteers who developed colds	2	1	2	3

Serological Response to Infection

Neutralization tests were performed on the sera from all the inoculated volunteers and from four volunteers who were given saline (Table IV).

The only significant titre rises—that is, of fourfold or greater—were found in 7 of the 13 volunteers who developed colds. Colds occurred in both those with and without antibody at the time of inoculation, but antibody rises were found mainly among those with a titre of 5 or less.

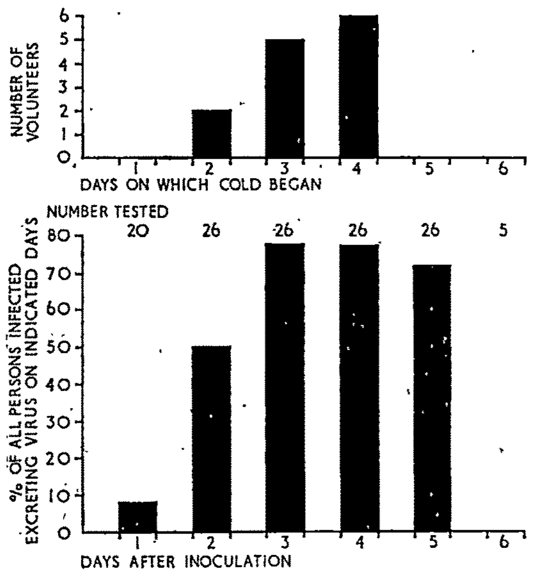

FIG. 2.—Time course of the onset of colds and the shedding of virus.

TABLE IV.—*Relation Between Antibody Titre and the Response to Inoculation*

Titre of Neutralizing Antibody in Serum Before Inoculation	No. of Volunteers in Indicated Category Who			Total
	Excreted Virus	Developed Colds	Developed Rising Antibody Titres	
≤5	7	6	4	8
5–	4	3	2	6
10–	6	3	1	8
40–160	1	1	0	4

Clinical Pattern of Colds Produced

The illnesses observed were all within the range of typical common colds. One was graded as severe (see Tyrrell, 1965), two as moderate, and the rest as mild. The main symptoms and signs are shown in Table V, alongside similar figures for volunteers infected with the B814 virus and with rhinoviruses. It can be seen that the pattern of illness was, in general, similar to that produced by the B814 virus. The proportion of colds produced by these viruses was not significantly greater than that produced by rhinoviruses, but the mean incubation period was significantly longer. The duration of illness was shorter, significantly so when B814 colds were compared with DC colds. On the other hand, there were no significant differences between the two strains of avian-infectious-bronchitis-like viruses or between the two types of rhinoviruses in these measurements.

The means of the peak numbers of handkerchiefs used were higher in colds due to avian-infectious-bronchitis-like viruses than in those due to rhinoviruses. Though the differences were not formally significant, the median values also were higher in avian-infectious-bronchitis colds than in rhinovirus colds. This was mainly due to the fact that very few people with colds due to avian-infectious-bronchitis-like viruses (1 out of 47) used fewer than eight handkerchiefs, while over a quarter (43 out of 155) did so among those infected with rhinoviruses. This difference is highly significant statistically. However, two volunteers, one infected with 229-E and one with B814, developed "streaming" colds, using over 100 paper handkerchiefs in one day. This was not seen after rhinovirus infections. Mucopurulent discharge was not seen at all after infection with 229-E, and, though this is unlikely to result solely by chance ($P=0.002$), the real significance is obscure. Malaise was more common than in rhinovirus colds and cough was less common, but these and other symptoms and signs were not significantly different in any of the groups. Over one-fifth of volunteers infected with 229-E had pyrexia, with an oral temperature between 99.2 and 100.4° F. (37.3 and 38° C.).

TABLE V.—*Clinical Features of Colds Produced by Inoculating Four Viruses*

	Avian-Infectious-Bronchitis-like		Rhinoviruses	
	229-E	B814*	Type 2 (HGP or PK)	DC*
No. of volunteers inoculated	26	75	213	251

Mild	10 (77%)	24 (71%)	63 (80%)	36 (47%)
Moderate	2 (15%)	7 (20%)	12 (15%)	28 (36%)
Severe	1 (8%)	3 (9%)	4 (5%)	13 (17%)

* Virus was administered only as nasal washings.

The statistical probability of some of the features of the colds due to 229-E virus n relation to colds due to other cold viruses are shown below.

(1) *t*-test on incubation periods	229-E : B814	$0{\cdot}3 > P > 0{\cdot}25$
	229-E : Rhino type 2	$0{\cdot}005 > P > 0\ 001$
	229-E : DC	$0{\cdot}05 > P > 0{\cdot}025$
	DC : Rhino type 2	$0{\cdot}498 > P > 0{\cdot}495$
(2) *t*-test on duration of colds	229-E : B814	$0{\cdot}15 > P > 0{\cdot}10$
	229-E : Rhino type 2	$0{\cdot}10 > P > 0{\cdot}05$
	229-E : DC	$0{\cdot}20 > P > 0{\cdot}15$
	B814 : Rhino type 2	$0{\cdot}10 > P > 0{\cdot}05$
	B814 : DC	$0{\cdot}01 > P > 0{\cdot}005$
	DC : Rhino type 2	$0{\cdot}95 > P > 0{\cdot}90$

Discussion

The fact that of the six isolations of this virus made by Hamre and Procknow five were from patients with clinical colds and only one from a healthy subject suggested strongly that the virus caused colds. Our results supplement these observations and show that after serial passage in tissue culture the virus can multiply in human respiratory epithelium in vitro and in vivo and can cause the common cold syndrome. Infection and disease occurred even when the serum contained substantial titres of neutralizing antibody, a phenomenon that has also been found on administering parainfluenza and respiratory syncytial virus to volunteers (Reichelderfer *et al.*, 1958 ; Tyrrell *et al.*, 1959 ; Kravetz *et al.*, 1961). The phenomenon might be due to lack of antibody in the nasal secretion of some persons with serum antibody, as appears to be the case with experimental infections with parainfluenza 1 virus (Smith *et al.*, 1966), but the possibility was not investigated in our studies.

There was no evidence of lower respiratory tract infection in our volunteers, but since the virus appears to infect children, as judged by the occurrence of serum antibody, it is nevertheless possible that the lower respiratory tract may be susceptible at that age and more serious disease may then be produced.

It is known that human sera often neutralize mouse hepatitis virus (Gledhill, personal communication). Furthermore, paired sera from 12% of Servicemen suffering from acute respiratory diseases have shown increasing antibody titres against mouse hepatitis virus (Hartley *et al.*, 1964), and it is possible that this occurred because some viruses of the avian-infectious-bronchitis-like group infect a significant proportion of such cases in the general population and induce the formation of antibody against the related virus. However, preliminary experiments have shown that our viruses are serologically distinct from avian infectious bronchitis and mouse hepatitis viruses on the basis of neutralization tests (Bradburne, Gledhill, and Berry, unpublished). There were no antibody rises against 229-E in sera from volunteers who developed colds after inoculation with B814, and the isolates of McIntosh *et al.* (1967) were also serologically distinct from 229-E. It therefore seems likely that we are dealing with members of a group in which individual viruses are very species-specific and in which those strains that infect man belong to a number of distinct serotypes. However, further studies are being made on these and related problems, and the results will be reported later.

Summary

A virus, 229-E, which morphologically resembles avian infectious bronchitis virus has been passed serially four times in man. Colds were produced in 13 out of 26 inoculated volunteers. There was a significant association between the presence of virus in the nose and the development of colds. Seven of the 13 volunteers who developed colds showed rising titres of antibody against this virus. The colds showed significantly longer incubation periods than did colds due to rhinoviruses, but no longer than those of colds caused by the related virus B814. The colds were also shorter and were associated with more nasal discharge than rhinovirus colds, but many of the differences are not statistically significant.

Of 215 sera collected from children and adults in Britain in the past 10 years 29% contained neutralizing antibody.

It is concluded that the virus can cause colds and probably circulates to a significant extent in this country.

We would like to thank the volunteers for their co-operation ; Miss E. M. Bullock for help with the clinical observations ; Dr. D. Hamre for providing the virus and serum ; Mr. S. Peto for advice on statistical problems ; and Mrs. P. K. Brown and Miss N. Frost for preparing the tissue cultures.

Acute Exudative Arthritis in Leprosy—Rheumatoid-arthritis-like Syndrome in Association with Erythema Nodosum Leprosum

A. B. A. KARAT,* M.B., B.S., B.SC., M.R.C.P., M.R.C.P.ED.; S. KARAT,† M.B., B.S., F.R.C.S.
C. K. JOB,‡ M.D., B.SC., M.C.PATH.; M. A. FURNESS,§ M.C.S.P.

Brit. med. J., 1967, **3**, 770–772

Erythema nodosum leprosum is a fairly common complication of lepromatous leprosy and is variously reported to occur in 30 to 40% of all patients with lepromatous leprosy on sulphone treatment (Buu Hoï and Basset, 1963; Cochrane, 1964; Job *et al.*, 1964). As yet there is no satisfactory explanation of the mechanism of production of erythema nodosum leprosum. Among the many hypotheses postulated, the concept of an immunological reaction as the fundamental basis of this rather dramatic complication is generally accepted (Aguas, 1963; Skinsnes and Tsang, 1963; Cochrane, 1964; Job *et al.*, 1964). There is some evidence to link up this phenomenon with autoimmunity, such as the presence of lupus erythematosus cell and rheumatoid factor in the sera of a proportion of these patients (Cathcart *et al.*, 1961; Bonomo *et al.*, 1965; Matthews and Trautman, 1965; Karat *et al.*, 1966). Pain in the joints (arthralgia) is a common and well-documented feature of erythema nodosum leprosum (Cochrane, 1964; Job *et al.*, 1964). Lele *et al.* (1965) described five cases of leprosy presenting as rheumatoid arthritis. Except for Case 4, none of their patients had erythema nodosum. The synovial biopsy was done in four out of the five cases, and the main histopathological finding was infiltration by round cells, epithelioid cells, and occasional giant cells. In the patient with erythema nodosum synovial biopsy did not reveal any significant change.

In the past two years at Schieffelin Leprosy Research Sanatorium we have seen 10 patients with lepromatous leprosy who developed acute painful exudative polyarthritis clinically similar to acute rheumatoid arthritis during the course of erythema nodosum leprosum. The polyarthritis cleared up completely when erythema nodosum subsided, leaving no residual signs of rheumatoid arthritis, clinical or radiological.

We present the case reports of two of these patients who, during the course of erythema nodosum leprosum, developed acute exudative polyarthritis clinically simulating acute rheumatoid arthritis; in both of them synovial biopsies were carried out during the acute phase. The nearest to the description of this condition we can find is that of Davison (1961) and of Wheate (1962). Wheate gives the case report of one patient who had a unilateral small effusion into the knee joint and "ganglion-like swelling of the synovia of both wrists on the dorsal aspects."

Case 1

A man aged 30 was admitted to hospital with a history of recurrent attacks of erythema nodosum leprosum for one year while on dapsone. He had had leprosy for four years. During the last two attacks of erythema nodosum leprosum he had noticed painful swelling of the small joints of the hands, knees, and ankles.

On examination he was seen to be ill with diffuse infiltration of the skin over the trunk, limbs, and face; slight enlargement of the ears; thinning of eyebrows; a normal nose; a large number of erythema nodosum leprosum lesions over the face, trunk, and limbs; and bilateral ulnar and lateral popliteal nerve enlargement. There was no motor paralysis, but sensory loss over the feet.

He had spindling of the proximal interphalangeal and metacarpophalangeal joints of the right hand and swelling of the right wrist, with palpable thickening of synovium (Fig. 1), and effusion into both knees (Fig. 2) and both ankle joints. All the affected joints were tender and there was painful limitation of movements of these joints.

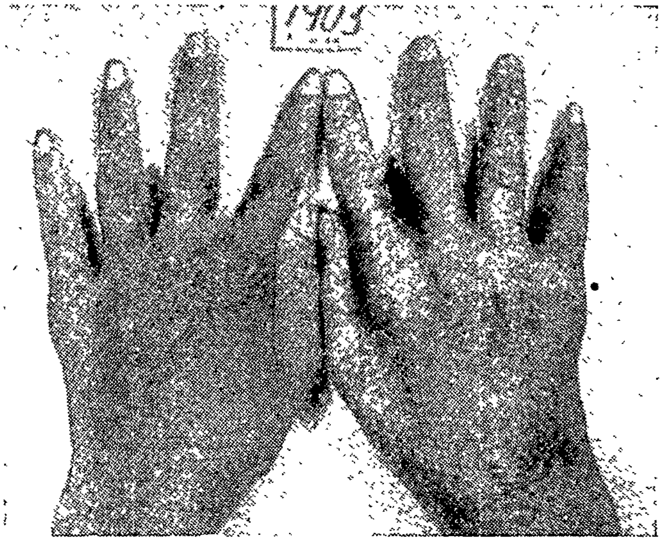

FIG. 1.—Case 1. Swelling of metacarpophalangeal and proximal interphalangeal joints of the right hand. Swelling of right wrist is also shown.

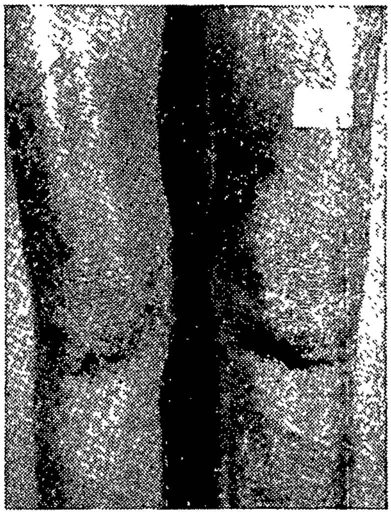

FIG. 2.—Case 1. Swelling of both knee joints, left more than right. There was effusion in both joints.

Investigations.—Haemoglobin 9 g./100 ml.; W.B.C. 21,000/cu. mm. (polymorphs 87%); erythrocyte sedimentation rate (Westergren) 32 mm. in first hour, 63 mm. in second hour; C-reactive protein four plus; antistreptolysin titre 333; Rose–Waaler test for rheumatoid factor (D.A.T.) 1:4; skin smears for acid-fast bacilli 1+ (Wade's method 0–6 scale); total plasma protein 7.3 g./100 ml. (gammaglobulin 1.6 g.); L.E. cells negative. *X*-ray examination of hands, wrists, knees, and ankles showed generalized osteoporosis. No subarticular erosions were seen. Synovial fluid: protein 1.8 g./100 ml. (globulin 0.78 g.); sugar 50 mg./100 ml.; W.B.C. 22/cu. mm. (polymorphs 75%). Direct smear: no organisms seen with Gram's stain and Ziehl–Neelsen stain. Synovial fluid was sterile on routine and acid-fast bacillus culture.

Schieffelin Leprosy Research Sanatorium, B.O. Karigiri, via Katpadi, N.A. Dist., S. India.

Synovial Biopsy from Left Ankle.—On exploration of the ankle synovial membrane was found to be congested and thickened. There was villous hypertrophy. Clear straw-coloured fluid in the joint was aspirated and a synovial biopsy was taken. Histological examination showed numerous proliferating capillaries surrounded by inflammatory cells consisting of plasma cells and lymphocytes. There were focal collections of histiocytes and diffuse polymorphonuclear leucocytic infiltration. Acid-fast stain showed no bacilli (Figs. 3 and 4).

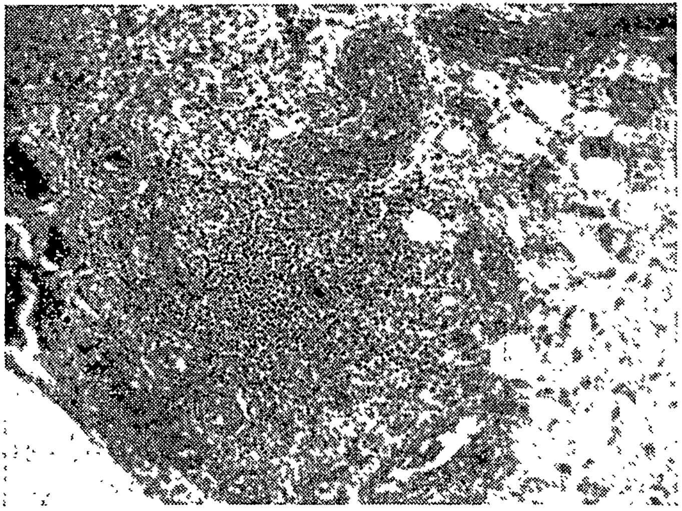

FIG. 3.—Case 1. Photomicrograph to show the synovial membrane densely infiltrated with inflammatory cells. There is marked increase in vascularity with proliferation of capillaries.

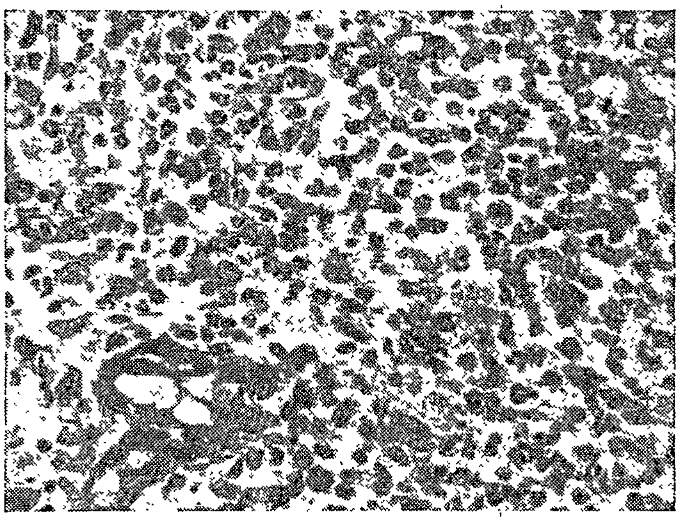

FIG. 4.—Case 1. High-power photomicrograph to show infiltration of synovial tissue with numerous polymorphs.

Case 2

A man aged 24 had had lepromatous leprosy for four years. He had been treated with dapsone for two years and during that time had had recurrent attacks of erythema nodosum leprosum. In the present attack he developed painful swelling of the metacarpophalangeal and interphalangeal joints of the hands, knees, ankles, and left elbow.

Examination revealed diffuse infiltration of the skin over the face, trunk, and limbs; erythema nodosum leprosum over trunk and face; loss of eyebrows; deformity of ears; partial collapse of the nose; enlargement of ulnar and lateral popliteal nerves on both sides with slight tenderness. There was no motor paralysis, but symmetrical loss of sensation in the feet.

He had spindling of proximal interphalangeal joints of fingers, and swelling of metacarpophalangeal joints, all of which were tender (Fig. 5); bilateral swelling of the knees, the right more pronounced than the left (Fig. 6); effusion into both the knee joints; painful limitation of movements of the knees; and painful swelling of and effusion into the right ankle joint (Fig. 7).

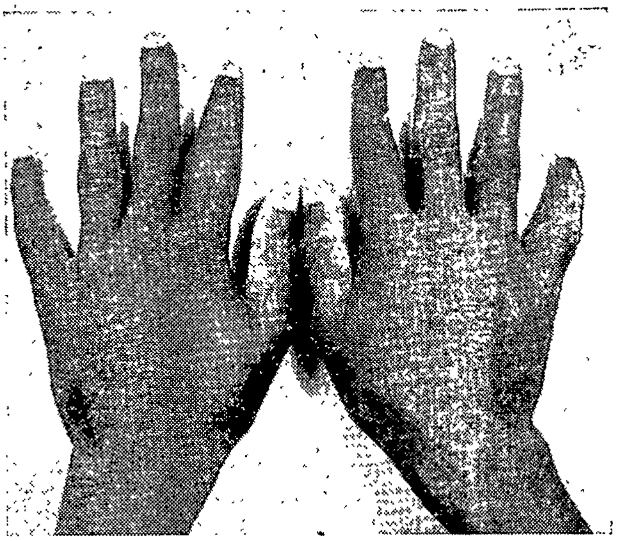

FIG. 5.—Case 2. Similar to Fig. 1. Spindling of fingers, more marked on the right. The right wrist is also swollen.

Investigations.—Haemoglobin 8.25 g./100 ml.; W.B.C. 11,000/cu. mm. (polymorphs 74%); erythrocyte sedimentation rate (Westergren) 116 and 138 mm. (first and second hours); C-reactive protein five plus; Rose–Waaler test for rheumatoid factor (D.A.T.) 1:32; skin smears for acid-fast bacilli 1.25+ (Wade's method 0–6 scale); total plasma protein 8.6 g./100 ml.; serum gammaglobulin 4.8 g./100 ml. (by paper electrophoresis method). No L.E. cells found on repeated examination. *X*-ray examination of hands, knees, ankles, and feet showed generalized osteoporosis. No erosions seen. Synovial fluid: W.B.C. 270/cu. mm., of which 45% were polymorphs; direct smear on Gram's stain did not show any organisms; Ziehl–Neelsen stain showed a number of acid-fast bacilli, most of which were granular. Synovial fluid was sterile on culture for routine organisms and acid-fast bacilli.

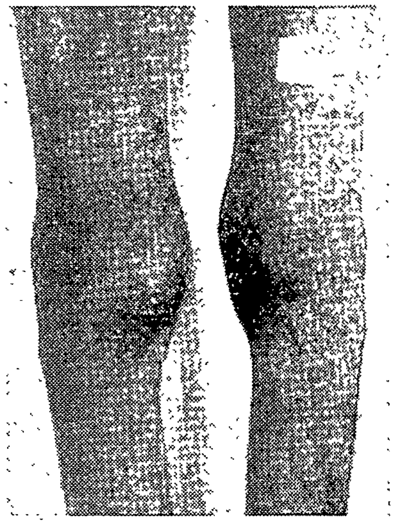

FIG. 6.—Case 2. Swelling of knees, the right more than the left.

Synovial Biopsy from Right Knee.—On exploration of the right knee the synovial membrane appeared thickened and congested. The synovial fluid was dark straw-coloured and opalescent. Histological examination of synovial tissue showed fibro-fatty tissue with marked increase in vascularity and an exudate consisting of fibrin and numerous polymorphonuclear leucocytes. There was marked tissue oedema. Acid-fast stain did not show any bacilli in the synovial tissue, but there were fragmented bacilli in a nerve present in the tissue. The entire appearance was typical of acute arthritis.

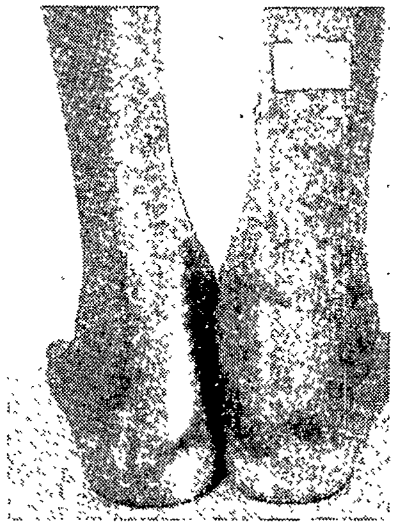

FIG. 7.—Case 2. Marked swelling of right ankle due to effusion into the joint.

Clinical Course and Management

The clinical course correlated very well with that of erythema nodosum leprosum—the acute arthritis either coincided with the onset of crops of erythema nodosum leprosum or followed its appearance in 24 to 48 hours. The joint manifestations cleared up 7 to 14 days after the subsidence of erythema nodosum leprosum. The usual measures, such as intravenous administration of 1% potassium antimony tartrate and oral chloroquine, were adequate to deal with the erythema nodosum leprosum, as well as the arthritis, at each subsequent episode of recurrence.

During the acute phase of arthritis local heat in the form of wax baths to the hands was very helpful in relieving pain as well as increasing the range of movement. Except during these periods of active physiotherapeutic measures, the affected limbs were immobilized in functional splints and maintained in elevation. Active exercises were encouraged as soon as the acute phase of the arthritis cleared up, to prevent flexion deformity and stiffness of the fingers.

Comment

General.—Arthralgia has been well recognized as a clinical manifestation of "reaction" in leprosy (Cochrane, 1964; Job *et al.*, 1964). An acute exudative polyarthritis occurring in association with these exacerbated phases has not been well documented. The clinical manifestations of this polyarthritis in leprosy closely simulate the acute phase of rheumatoid arthritis and may be mistaken for the latter. Unlike rheumatoid arthritis, the clinical manifestations in the joints clear up when the erythema nodosum leprosum resolves, without any residual damage or manifestations in the affected joints—as seen so far during a two-year follow-up of most of these patients. The synovial fluid, which had the biochemical features of a transudate, was sterile on culture, both for pyogenic organisms and for acid-fast bacilli. The Rose–Waaler test for rheumatoid factor was positive in one of the two cases described here and in 6 of the 10 patients we have so far observed. The joints most commonly affected were the small joints of the hands—the metacarpophalangeal and the proximal interphalangeal joints—the knees, and the ankles. Effusion into the knees and ankles was common.

Age and Sex.—Both patients (Cases 1 and 2) were young men. We have seen this syndrome in 10 patients, of whom only one was female. This is in striking contrast with the usual higher incidence of rheumatoid arthritis among young women (Robinson, 1963). On the whole, erythema nodosum leprosum occurs less commonly in women and is usually not as severely disabling as in men (personal observation). This may explain the rarity of the syndrome among women leprosy patients.

Disease and Its Complications.—All the patients had lepromatous leprosy of longer than three years' duration. In all of them the "rheumatoid syndrome" occurred only after recurrent episodes of erythema nodosum leprosum. We have not seen this syndrome during a first attack, nor in association with mild erythema nodosum leprosum. In all the patients there was involvement of skin and the subcutaneous tissues in the erythema nodosum leprosum process. Every one of them had systemic manifestations of fever, anorexia, and general malaise.

Histopathology of the Synovium.—In the affected joints this is of considerable interest and helps to substantiate the suggestion that this acute exudative "leprous" polyarthritis is different from acute rheumatoid arthritis. In this condition there is well-marked infiltration of the synovial membrane with polymorphonuclear leucocytes, and the joint cavity shows an exudate of fibrin with numerous polymorphs entangled in it. The acute inflammatory reaction in the synovial membrane is very similar to that seen in the coexistent erythema nodosum lesions found elsewhere in the body. This is in contrast with the lymphocytic and plasma cell infiltration of synovium which characterizes rheumatoid arthritis (Anderson, 1957).

It is interesting to note that none of our cases—the two reported here and the other eight cases we have so far observed—had lupus erythematosus cells. Whether these joint manifestations are "autoimmune" is open to debate. It seems as though the pathogenesis of these acute joint manifestations is linked with that of erythema nodosum leprosum, and elucidation of one should help in the understanding of the other.

Summary

The clinicopathological features of exudative polyarthritis simulating acute rheumatoid arthritis occurring in two lepromatous leprosy patients in association with erythema nodosum leprosum is, so far as we are aware, described for the first time.

It is suggested that erythema nodosum leprosum and the exudative polyarthritis occurring together may be aetiologically determined by an immunological phenomenon.

We gratefully acknowledge the continued financial support from the Leprosy Mission, London, and the American Leprosy Missions Inc., New York. We are also grateful to Mr. Japes Fowler, Mr. Cyril Prathapkumar, and Mr. Paul Rajasingh for technical assistance; to Mr. Christopher Dorairaj for the photographs and *x*-ray films; to Dr. Grace Koshy, Associate Professor of Bacteriology, Christian Medical College and Hospital, Vellore, for estimating the antistreptolysin titre and C-reactive protein; and to Mrs. L. Furness for secretarial assistance.

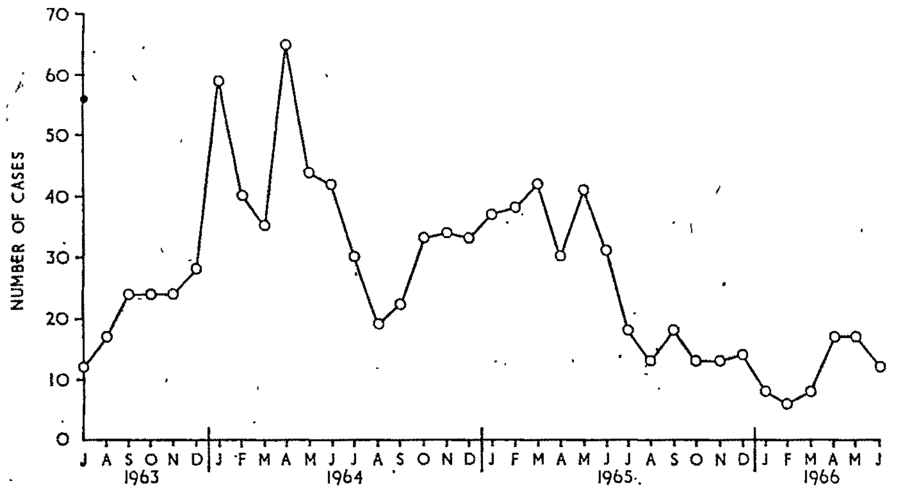
Infectious Hepatitis in Leicester 1963-6

C. BURNS,[*] M.B., CH.B., D.C.H., D.P.H.

Brit. med. J., 1967, 3, 773–776

During the latter part of 1962 the Leicester City Health Department became aware of an increasing incidence of infectious hepatitis among schoolchildren, and on 1 July 1963 the disease was made notifiable in Leicester by an order under Section 147 of the Public Health Act, 1936. This order was to run initially for a three-year period, ending on 30 June 1966, but has been extended for a further three years.

A marginal punch card was devised in conjunction with Kalamazoo Limited to record details of cases, and full information regarding each notified case was obtained at special home visits carried out by health visitors or clinic nurses. During the three-year period 961 cases were notified, and this paper presents an analysis of the epidemiological features of the outbreak. A preliminary analysis of information collected during the first 16 months has already been published (Burns, 1965).



Monthly incidence of infectious hepatitis in Leicester, July 1963 to June 1966.

Epidemic Pattern

General Course of Outbreak

The accompanying Chart shows the monthly incidence of the disease over the three years from 1 July 1963, and indicates that notifications continued at a high level throughout 1964 and during the first half of 1965, but began to fall in the second half of 1965 and remained low throughout the remainder of the period.

Long-term variations in the incidence of the disease with epidemic periods similar to that in Leicester, separated by intervals of several years of low incidence, have been reported from many areas, notably by Mosley *et al.* (1963) in Des Moines, Iowa, and on a national scale by the U.S. Department of Health, Education and Welfare (1964a, 1964b, 1964c). The Chief Medical Officer to the Ministry of Health (1965) showed a similar pattern for the Eastern Region of England and Wales, where the disease has been notifiable since 1943.

Seasonal Variation

A seasonal variation in incidence was, as the Chart shows, well marked in both 1964 and 1965, with maximum notifications in late winter and high incidence continuing into the spring. A seasonal trend has often been remarked on in this disease (Mosley *et al.*, 1963 ; Bothwell *et al.*, 1963).

Age and Sex Variations

In this as in other outbreaks (Bothwell *et al.*, 1963 ; Ward and Krugman, 1962) the disease affected the sexes more or less equally. There was a marked preponderance of cases in the 5–14 age groups, 73.2% of the cases being children in this group. This also is in line with many previous reports (Bothwell *et al.*, 1963 ; U.S. Department of Health Education and Welfare, 1963), though a predominance of cases in adults has been reported in outbreaks occurring in Denmark (W.H.O. Secretariat, 1964) and in Canada (Bothwell *et al.*, 1963).

Table I shows that the proportion of cases in children under the age of 15 years fell markedly during the final 12 months of the three-year period, coincident with a substantial fall in the number of notified cases as compared with the two previous years. A similar trend has been noted by other observers (U.S. Department of Health Education and Welfare, 1963 ; W.H.O. Secretariat, 1964). It would appear that this pattern is related to the fact that, in epidemic periods, children under the age of 15 number about three-quarters of the cases, and when a sufficient proportion of them have been infected either clinically or subclinically, and presumably acquired immunity, the incidence of the disease falls to non-epidemic levels, to rise once more when a new generation of susceptibles appears.

Geographical Distribution

During the three-year period cases occurred in all parts of the city. At various stages of the epidemic sizable local aggregations of cases were apparent in particular areas. These formed fairly well defined localized outbreaks, extending over periods of perhaps six to nine months. These local outbreaks tended to involve densely populated parts of the city, of relatively low socio-economic status. The south-eastern quarter

[*] Divisional Medical Officer, St. Albans Division, Hertfordshire County Council; late Deputy Medical Officer of Health for the City of Leicester.

of the city, which comprises the more favoured residential suburbs, was almost completely spared. Table II shows the 961 cases notified, broken down into quarterly notifications in each of the city's electoral wards, together with certain additional information derived from the 1961 census report, regarding the ward population and the density of occupation of living accommodation.

Correlation coefficients were calculated between the attack rates per thousand based on the 1961 population figures and the two indices of population density derived from the same source, and gave figures of 0.784 between the attack rate per thousand and the percentage of persons living at more than 1.5 per room and 0.778 between the attack rate per thousand and the average number of persons per room. Both these coefficients are highly significant.

This procedure is, of course, imperfect and open to the dual criticism that neither the population figures from which the attack rates are calculated nor the indices of density of occupation are precisely contemporaneous with the occurrence of the cases. Examination of the annual records of numbers of electors registered in the 16 wards shows, however, that, allowing for alterations in ward boundaries, changes during the period concerned are small in relation to the correlation coefficients, and it is safe to draw the conclusion that the incidence of the disease is closely related to household congestion. Mosley *et al.* (1963) made similar observations on the association of high incidence of the disease with large congested households of low socio-economic status, and it is significant that in Leicester the largest number of cases and the highest attack rate occurred in Ward 16, which at the 1961 Census had the highest occupation densities. This ward consists almost entirely of a single large council estate, populated in the main by large families of low socio-economic status.

A further possible criticism is that as almost three-quarters of the cases occurred in the age group 5–14 years the apparent correlation between attack rates and domestic congestion may merely be a reflection of the possibility that the wards with the highest indices of overcrowding were also those with the highest proportions of children in their populations. Attack rates for the age group 5–14 years were therefore calculated for each of the 16 wards from data from the 1961 census, and the correlations between these rates and the congestion indices are respectively: (*a*) with the percentage of the population living at greater density than 1.5 per room, 0.877 ; (*b*) with the average number of persons per room, 0.524. Both these correlations remain significant, and in particular the high correlation between attack rates in the 5–14 age group and the percentage of the population living at more than 1.5 per room reinforces the conclusion that infectious hepatitis is a disease associated with overcrowding and underprivilege.

Mode of Transmission

The epidemiological pattern indicated direct person-to-person transmission as the mode of infection. This is the mode of spread in the majority of epidemics—for example, in Bristol (Bothwell *et al.*, 1963) and Des Moines, Iowa (Mosley *et al.*, 1963). Outbreaks have, however, been described in which both food and water have been the apparent vehicle of spread (*Lancet*, 1962, 1964 ; *Brit. med. J.*, 1964). In the U.S.A. clams and oysters have been incriminated in a number of outbreaks (U.S. Department of Health, Education and Welfare, 1964a, 1964b).

While no general attempt was made, except as regards food-handlers who were family contacts of known cases, to detect anicteric or subclinical cases, it was evident that such cases were a frequent source of infection to others. MacCallum (1961) quotes estimates of the ratio of anicteric to icteric cases of up to 10:1. In the Leicester outbreak the part played by subclinical cases in transmitting the disease manifested itself when, as happened occasionally, one or more cases occurred in a family where the only history of contact with a previous known case of the disease was in another member of the family who did not suffer an overt attack. Another index of the important part played by asymptomatic and unrecognized cases in the spread of the disease was the fact that of the 961 cases 638 (66.4%) were unable to recall any contact with a known case of the disease.

Spread within the Family

The 961 cases occurred in 742 households. In the affected households 36.2% of the children and 9.6% of the adults contracted clinical attacks of the disease. These figures compare very closely with those of Bothwell *et al.* (1963), who found in the Bristol outbreak that 39% of children and 10.3% of adults in affected households fell ill.

The secondary attack rate among child family contacts was 11.8% and among adults 1.9%. Mosley *et al.* (1963) reported a secondary attack rate of 10% among family contacts not protected with gammaglobulin.

School Spread

There are 185 schools in the city and cases occurred in 115 of them. In 62 schools there were fewer than five cases, 25 had more than 10 cases, and nine had more than 20 cases. These nine schools between them produced 267 cases—that is, more than a quarter of the total number of cases in the city and more than one-third of the cases among schoolchildren.

The fact that more than half of the affected schools produced fewer than five cases each and 17 (14.8%) of them produced only one case is in striking contrast to the high incidence in the relatively small number of schools in which substantial outbreaks occurred. The reason for the great differences in the epidemiological pattern of the disease observed in different schools is obscure, but it does not appear to be related to factors within the school, such as adequacy of sanitary or washing facilities. The wide variation in the natural history of school outbreaks makes the evaluation of preventive measures, such as mass gammaglobulin administration or the institution of stringent hygienic measures as described by Schofield (1964), extremely difficult, and underlines the need for carefully controlled trials before conclusions are drawn regarding the efficacy of such measures and the circumstances in which they should be applied.

As already stated, the great majority of cases were children of school age. Within this group, however, there was a marked difference between the primary and secondary age groups. All nine schools with sizable outbreaks were primary schools, and when cases occurred in primary schools a substantially larger proportion of the children tended to fall ill than in a secondary school. At schools where cases occurred the overall attack rates were: primary 2.8%, secondary modern 1.2%, and grammar 0.5%. The difference between secondary modern and grammar school attack rates is striking, and a number of factors, including smaller classes in grammar schools, the presence in them of a proportion of young people aged 16 years and over with a less tendency to the disease, and, of course, differences in socio-economic background, may have contributed to this.

Outbreaks of infectious hepatitis have often been associated with schools and have characteristically smouldered on for several months, with shorter periods of explosive incidence within the outbreak. Tilley (1960), Flanagan and Lister (1962), Schofield (1964), and Yarrow (1964) have described such outbreaks in recent years, while Pickles (1939) stressed the role of school contact in the occurrence of outbreaks. On the other hand, Mosley *et al.* (1963) stated that in the outbreak in Des Moines, Iowa, examination of the role of the school indicated that the school, particularly the classroom, was not the primary source of infection, and that closer social and personal contact was necessary for transmission of infection to occur than was afforded by casual classroom association.

In the Leicester outbreak a close examination was made of 43 cases occurring at an infant school of 508 pupils, giving an attack rate of 8.44%. In these 43 cases the apparent source of infection was: known classroom contact, 34.9%; family/household contact, 22.1%; probable subclinical class contact, 10.5%; unidentified, 32.5%. In addition, all cases occurring in the families of these 43 children were examined, and of the 61 cases involved the apparent source of infection was: known classroom contact, 27.9%; family/household contact, 31.2%; probable subclinical class contact, 6.6%; unidentified, 34.3%.

The small numbers and the high proportion of cases of unidentified origin do not permit the drawing of conclusions on the relative importance of classroom as opposed to family contact in the transmission of the disease, but it does seem clear, in contrast with the findings of Mosley *et al.*, that contact in the classroom was a factor of considerable importance.

School Meals

The possibility of school meals being implicated in the spread of the disease was thoroughly investigated and there was no evidence that they were a factor. Of the 776 cases occurring among schoolchildren 336 (43.3%) took school meals, while of the total of 37,941 pupils in the schools where cases occurred 19,966 (52.6%) took school meals. Of the 19,966 children taking meals 336 (1.7%) suffered attacks, while of the 17,975 not taking meals 440 (2.5%) suffered attacks.

Clinical Features and Prognosis

Jaundice occurred in 91% of notified cases. Reference has already been made to the substantial numbers of anicteric cases and symptomless excreters of virus which are believed to occur during any outbreak, the present one being no exception. It was obvious that many anicteric cases were occurring among both school and family contacts, but no general attempt was made to search for them. The absence of any specific serological or virological test for the presence of infection is a most serious handicap in detecting such cases. The use of tests for the presence of bilirubin in the urine has been suggested (*Brit. med. J.*, 1963b) as a means of detection, and a number of such tests were carried out in the current investigation in family or school contacts who displayed symptoms but no clinical jaundice. The results were all negative: 44 (4.6%) of the cases required admission to hospital and 31 (70.5%) of these were between the ages of 5 and 14 years, while 9 (20.5%) were aged over 20 years. Three of the cases were fatal. An Indian immigrant woman aged 32 died in hepatic coma after a three-weeks illness; a schoolboy aged 5 years died of subacute liver failure after a six-weeks illness; and a 9-year-old boy died in hepatic coma after eight days. These three deaths represent a mortality rate of 3.1 per thousand.

Sherlock (1963) stated that the mortality in large outbreaks of infectious hepatitis has been generally quoted as one to two per thousand. In the Bristol outbreak (Bothwell *et al.*, 1963) there were three deaths in 2,107 cases. Occasionally, however, outbreaks have been reported with higher mortality. The *Lancet* (1962) referred to an outbreak in New Jersey in 1961 where there were 2,095 cases with 34 deaths.

There is some evidence (*Brit. med. J.*, 1963a) that cirrhosis may occasionally follow infectious hepatitis, but Sherlock (1963), reviewing the question of long-term sequelae, concluded that rapid and complete recovery is the rule, and while transition to cirrhosis does occur it is infrequent. Bothwell *et al.* (1963) reported that early follow-up studies of their cases appeared to confirm the rarity of prolonged ill-health or cirrhosis.

Discussion

Infectious hepatitis has been described as one of the biggest unsolved problems in medical virology (*Brit. med. J.*, 1964). The epidemiological features of the disease have been studied extensively in the United States, where the Department of Health, Education and Welfare has published a series of surveillance reports since April 1960, and in a number of European countries. In 1964 a symposium on viral hepatitis sponsored by the W.H.O. Regional Office for Europe was held in Prague. Seventeen countries including the U.K. were represented at this symposium, at which the clinical, laboratory, epidemiological, and control problems presented by the disease were reviewed and the setting up of detailed surveillance programmes in the different European countries was recommended.

So far as the United Kingdom is concerned, the disease is not generally notifiable, so that the magnitude of the problem it presents is unknown, and no information regarding its epidemiological pattern on a national scale is available. Local studies, including that carried out in East Anglia under the Jaundice Regulations, 1943 (MacCallum *et al.*, 1951), the reports by Bothwell *et al.* (1963) on 2,101 cases which occurred in Bristol in 1961–2, and by Clayton (1967) on his survey at Coventry, together with numerous reports of local outbreaks in schools or other communities (Tilley, 1960; Flanagan and Lister, 1962; Schofield, 1964; Yarrow, 1964; Pollock, 1964), and, of course, the classical studies of Pickles (1939), clearly indicate that in this country a considerable amount of ill-health is being caused by this infection, more especially among schoolchildren, and that an unknown though probably small amount of permanent liver damage also results from it.

The control of the disease presents peculiarly difficult problems. Not only do large numbers of anicteric or subclinical cases occur which, though remaining undiagnosed, are nevertheless infectious, there is evidence (MacCallum *et al.*, 1951; Ward and Krugman, 1962) that patients are infectious during the incubation period, about 20 days before the onset of jaundice. The incubation period itself is long and variable—up to six or eight weeks, and cases may follow each other in a family, separated by this interval. Furthermore, there is evidence that some patients continue to excrete virus for long periods after clinical recovery. Ward and Krugman (1962) quoted evidence of the finding of virus in the stools up to 15 months after the onset of illness. Despite the work of Rightsel *et al.* (1961) there is no simple laboratory method of detecting the presence of virus and no specific test for the carrier state. In food- or water-borne outbreaks, if the source can be traced and appropriate measures taken, good results may be obtained. In contact-spread outbreaks, on the other hand, it is doubtful whether at the present time effective control measures are possible.

The epidemiological features already referred to, together with the absence of any specific laboratory test for the carrier state, clearly render quarantine of contacts of no practical value, and this is confirmed by the work of Kostrzewski and Szmunes (1964). It seems reasonable to keep contacts who are food-handlers under surveillance for a period, and in Leicester such surveillance is maintained until six weeks has elapsed after the onset of illness in the last case in the family. Bothwell *et al.* (1963) excluded food-handlers in the school meals service for a period of one month if they were well; but this seems arbitrary and difficult to justify in view of the facts stated above. In Leicester these persons are kept under surveillance, their urine is tested weekly with the Ictotest tablet, and blood is taken for serum alanine aminotransferase estimation.

Schofield (1964) described an outbreak affecting two primary schools which was apparently abated by the introduction of stringent measures of hygiene, including special supervision of the children's handwashing, and disinfection thrice daily of all W.C. seats, flush-handles, washbasin taps, and door-handles. Similar measures were used at schools in Leicester where outbreaks occurred, but without noticeable effect.

Evidence is available (Ward and Krugman, 1962; Mosley *et al.*, 1963) of the efficacy of gammaglobulin in the U.S.A. in providing passive protection against a clinical attack of infectious hepatitis and similar claims have been made in respect of British gammaglobulin. However, properly controlled trials have hitherto been lacking in this country, and the need for caution in drawing conclusions from uncontrolled trials in view of the wide variations in the natural history of school and other institutional outbreaks has already been referred to. A controlled trial at present being carried out by the Epidemiological Research Laboratory, Colindale, will, it is hoped, clarify this question.

Future progress in the control of this disease would appear to lie in two directions. Firstly, the introduction of a simple and reliable test for the presence of the virus, and, secondly, the production of an effective vaccine. In the meantime there is a good case for general notifiability, at least for a period, in order to extend knowledge of the incidence and epidemiological pattern of the disease in this country, and so to provide the facts on which the use of improved control measures can be based when they become available. The whole problem may acquire much greater urgency if the suggestion made by Stoller and Collmann (1965) of an association between infectious hepatitis and Down's syndrome should be substantiated.

Summary

During the three years 1 July 1963 to 30 June 1966 961 cases of infectious hepatitis were notified to the Leicester City Health Department. The peak of the epidemic occurred during the first two years of that period. A well-marked seasonal trend, with maximum incidence in late winter and spring, was observed. Over the whole period more than three-quarters of the patients were aged under 15 years, children in primary schools being the most heavily affected group. As the intensity of the epidemic waned the proportion of child cases tended to fall. There was a significant association between high incidence of the disease and domestic overcrowding and poor living standards. There was evidence that anicteric and subclinical cases played a large part in the spread of the disease. The overall secondary attack rate among family contacts was 5.44%. Among children the rate was 11.8% and among adults 1.9%.

Cases occurred in 115 of the 185 schools in the city, but in the great majority of schools no extensive outbreak developed. The natural history of the disease as it affected schools showed wide variations, and there was no means of distinguishing in advance the small minority of schools in which the initial cases were followed by a sizable outbreak from those where only a small number of cases occurred. This makes the evaluation of both the efficacy of preventive measures, such as the administration of gammaglobulin, and the circumstances in which they should be used very difficult. Both family and school contact were important in transmitting the disease; there was no evidence, however, that school meals were a factor. Most of the cases had illnesses of mild or moderate severity, but three (3.1%) died.

I wish to thank Dr. B. J. L. Moss, Medical Officer of Health, City of Leicester, for his encouragement; the health visitors and clinic nurses of the Leicester City Health Department for their work in carrying out the domiciliary inquiries; and the clerical staff of the department for their indefatigable help with the analysis and tabulation of the data. Gratitude is also due to Mr. A. Lawrence, of the Leicester University Mathematics Department, Miss K. Wolfendale and Mr. G. Raymont, of the Leicester College of Technology, and Mr. V. A. Dickinson, of the Hertfordshire County Health and Welfare Department, for advice and assistance with statistical analysis.

Natural History of Refsum's Syndrome in a Gloucestershire Family

A. M. G. CAMPBELL,* D.M., F.R.C.P. ; E. R. WILLIAMS,† M.A., M.B., M.R.C.P.

Brit. med. J., 1967, 3, 777–779

Thirty-nine cases of Refsum's syndrome (Refsum, 1946) or heredopathia atactica polyneuritiformis have now been reported (Carrell *et al.*, 1966). The neurological features—namely, a mixed sensory and motor peripheral neuropathy, atypical retinitis pigmentosa with night blindness and constricted visual fields, cerebellar ataxia, and nerve deafness—are well attested and have been recently reviewed (Alexander, 1966), while abnormalities occurring outside the central nervous system include ichthyosis, epiphysial dysplasia, and cardiomyopathy (Gordon and Hudson, 1959). The disease is inherited as an autosomal recessive (Refsum, 1946) and most cases have occurred in consanguineous families.

The discovery of an excess of phytanic acid (3, 7, 11, 15-tetramethylhexadecanoic acid) in the serum and tissue lipids of these patients (Klenk and Kahlke, 1963 ; Eldjarn, 1965) has opened several exciting fields of speculation regarding the natural history of this disease, the aetiology of which is now partly understood. This has led us to investigate further a family living in the Forest of Dean area of Gloucestershire. Two members of this family have Refsum's syndrome and have been followed by one of us (A. M. G. C.) since 1958 and 1960 respectively.

We wish to report the results of a clinical and biochemical survey of three generations of the family, to record abnormalities in phytanic acid content of the cerebrospinal fluid (C.S.F.) in one of the patients, and to comment on the marked fluctuation in the clinical course of the disease, which was paralleled by variations in levels of C.S.F. protein.

Case 1

The patient, a man now aged 28, was first seen in 1958 at the age of 19, complaining of weakness of the limbs and unsteadiness and difficulty in walking, which had become worse after a febrile illness.

Since the age of 7 he had been noticed to be unsteady and had never been able to play games at school. At 14 he saw an orthopaedic surgeon because of pes cavus, and his mother stated that his feet had been deformed since he started to walk ; at this time he first noticed deafness. In September 1957 he had "Asian" influenza and a fortnight later developed weakness, numbness, and tingling of the limbs and slurred speech. He was admitted to a near-by hospital and was first thought to have an infective polyneuritis, as the C.S.F. protein was over 300 mg./100 ml.

When first seen he was found to have a severe peripheral neuropathy with absent reflexes, marked wasting of the hands and lower legs, and a glove-and-stocking anaesthesia to all sensory modalities. He also had bilateral nerve deafness, ataxia and intention tremor, clawing of the feet, and atypical retinitis pigmentosa (Fig. 1) with some degree of optic atrophy. The pupils were small, but reacted to light and accommodation. The visual acuity was 6/9 R and 6/6 L and there was a generalized constriction of the visual fields.

The patient has been followed over the past eight years and his disease has taken a variable downhill course. Over this period he has been extensively investigated ; haemoglobin, white blood count, erythrocyte sedimentation rate, serum electrolytes and urea, fat balance, xylose excretion, electroencephalogram, urinary porphyrins and amino-acids, urinary ketosteroid excretion, and skull and chest radiographs had all been normal. The serum cholesterol was 150 mg./100 ml., serum lipids were 0.71 g./100 ml., and serum α_2-globulin just increased at 0.9 g./100 ml. (liver-function tests were otherwise normal). The electrocardiogram was normal in 1958, but by 1966 there were flat T waves over the lateral chest leads. Foot radiographs (Fig. 2) showed metatarsal dysplasia with an equinovarus deformity and shortening of all the metatarsals except the second. Electromyography revealed only changes associated with a reduced muscle mass, and muscle biopsies showed fibrosis. The C.S.F. was at normal pressure with no increase in cells, and was

a pale yellow; the protein was consistently greatly raised, ranging from 368 to 732 mg./100 ml. A great excess of globulin was present. It seemed possible that exacerbations of the disease were associated with a rise in C.S.F. protein (Fig. 3).

Between February and August 1966 he worsened steadily and became unable to walk at all in spite of being on a low phytol diet, but between October 1966 and February 1967 there was a great improvement, particularly in motor power peripherally, so that he was able once more to write and type, and could walk without assistance and control his invalid motor vehicle. During this period the only dietary reduction imposed was the avoidance of green vegetables and fat meat.

Case 2

A married sister, aged 33, of the previous patient had a healthy childhood and adolescence, though mild deformity of the feet was noted by her mother. At the age of 20 she developed an acute weakness of the limbs and unsteadiness, again following a febrile illness. She was thought to have poliomyelitis and was admitted to hospital, where she was found to have weakness of the right arm and both legs, absent tendon jerks, ataxia of all limbs, and impaired vibration sense in the legs. A diagnosis of infective polyneuritis was again made, supported by a C.S.F. protein level of 400 mg./100 ml. She slowly improved; at the age of 22 she married and has two daughters, aged 6 and 8. During both pregnancies she thought she was noticeably weaker and more ataxic. In 1963, when aged 30, she had a total hysterectomy for menorrhagia with conservation of the right ovary. After this she again became weak and unsteady but improved in a few months, and since 1964 has remained well able to cope with her household duties, and feels that she has steadily improved. Neither this patient nor her brother has shown any mental deterioration.

When examined in 1966 she was a good deal better than when we saw her in 1960. She had bilateral cerebellar signs, bilateral drop-foot with absent ankle jerks and mild wasting of the hand and foot muscles, and claw-feet similar to her brother's, with the same atypical retinitis and nerve deafness. The C.S.F. protein had dropped to 83 mg./100 ml., radiographs of the tarsal bones were normal, and her disease was clearly not so severe as that of her brother.

Family Study

The family tree of the three generations studied is given in Fig. 4. The family are of yeoman stock and live in a small Gloucestershire town. There is no history of any other familial disease and no suggestion of consanguinity; while I 1 traces his ancestry back through four generations of Forest of Dean dwellers, I 2 is a native of Cheltenham. There is no consanguinity in any of the spouses of the sibs of the propositi.

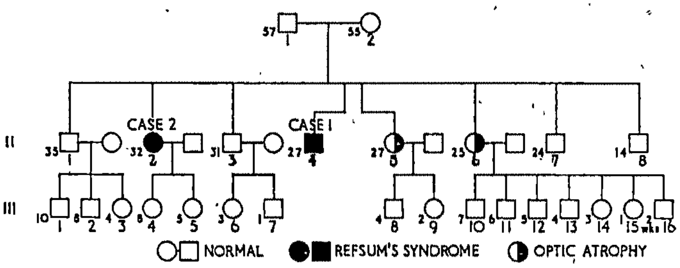

FIG. 4.—Family tree.

All the subjects shown in the family tree were examined. Two sisters (II 5 and 6) were found to have a mild optic atrophy and II 6 had a retinal cyst. No abnormality was found in any others, and in particular none of the third generation had retinitis pigmentosa, ataxia, or clinical evidence of bone disorder.

Serum from everyone in the family was examined for the presence of phytanic acid, but with the exception of the propositi this was absent in all of them. Creatine phosphokinase activity and serum caeruloplasmin levels were also estimated in the propositi and eight relatives (see Table). It can be seen that the creatine phosphokinase is raised in both the propositi, as might be expected in any wasting disease (Gubbay *et al.*, 1966). The serum caeruloplasmin was raised in Case 1 and also in his younger sister (II 6), who had optic atrophy, though not in his twin sister.

Biochemical Findings

	Age	Phytanic Acid (% of Total Fatty Acid)	Creatine Kinase (i.u.)	Caerolo-plasmin (mg./100 ml.)
I 1	57	0	11	5·3
I 2	55	0	16	13·1
II 1	35	0	20	10·6
II 2 (Case 2) ..	32	15·6	90	18·9
II 3	31	0	15	10·5
II 4 (Case 1) ..	27	34·7	68	26·0
II 5	27	0	13	8·8
II 6	25	0	8	32·8
II 7	24	0	18	5·0
II 8	14	0	56	10·6
Normal controls		0	Males up to 66 Females up to 43	14·25

Phytanic Acid

The propositus (Case 1) was shown to have a very high level of phytanic acid in the serum. This was estimated by gas-liquid chromatography in Oslo (Eldjarn, personal communication, 1966) to be 90 mg./100 ml. of serum, a value among the highest so far found in this condition by these workers. An aliquot of the same sample was found to contain phytanic acid in a concentration of 34.7% of total serum fatty acids by Professor J. N. Cumings. A sample of serum taken in 1960 and freeze-dried contained 12% of the total fatty acids as phytanic acid.

In Case 2 the serum contained 15.6% of the total of fatty acids as phytanic acid (July 1966) and 14.3% when re-estimated in February 1967.

C.S.F. samples from both propositi were also examined. A freeze-dried specimen taken from Case 1 in 1960 contained phytanic acid in a concentration of 10% of total fatty acids. A specimen taken in August 1966, when the disease had progressed considerably, contained 19.4%. No phytanic acid was demonstrated in the C.S.F. in Case 2, however. These 1966 C.S.F. specimens were also subjected to phospholipid estimation and protein electrophoresis and showed markedly raised total phospholipid, lecithin, and globulin values.

Discussion

The elevated phytanic acid levels here reported are in accordance with previous studies (Kahlke, 1964; Eldjarn, 1965; Rake and Saunders, 1966), and it now seems established that the clinical features of the disease are associated with an impairment of oxidative degradation of this branched-chain fatty acid (Eldjarn *et al.*, 1966). Though an excess of phytanic acid has been found in many tissues, including liver, kidney, brain, nerve, skeletal muscle, and urine (reviewed by Rake and Saunders, 1966), C.S.F. levels have not previously been recorded.

The family study shows that the inheritance demonstrated is compatible with an autosomal recessive mode of transmission. Kahlke and Richterich (1965) found higher amounts of phytanic acid in the serum of the apparently healthy mother of a patient with Refsum's syndrome than the serum of the patient; this raises the possibility of a biochemical abnormality being demonstrable in heterozygous carriers of the disease, a situation akin to that in thalassaemia or in glucose-6-phosphatase deficiency—Von Gierke's disease (Cori and Cori, 1952). This would be of importance in genetic counselling, but we found no phytanic acid in the serum of any relatives, confirming the findings in the parents of two Norwegian cases of Refsum's syndrome (Eldjarn, personal communication, 1966).

The remarkable variability of the clinical course of Refsum's syndrome is now well known. Of Refsum's original cases, one presented after an acute febrile illness, and one apparently began as a sequel to the physical exertion of fishing near the Lofoten Islands. In both cases the worsening immediately after a febrile episode had led to their first hospital admission. Another of Refsum's cases relapsed regularly in the springtime; in the light of our present knowledge it is tempting to speculate that this might have been associated with seasonal dietary variations. A member of one of Refsum's original families has recently been reported to have improved after long-term mental hospital admission, possibly again associated with low vegetable intake (Eldjarn *et al.*, 1966). Following preliminary reports on the value of a diet low in phytanic acid Eldjarn *et al.*, 1966) in the condition, this diet was given to our Case 1, but without improvement. Because of the patient's intolerance the diet was relaxed, and on moderate restriction he was at the time of writing showing steady improvement.

A fluctuation in C.S.F. protein was evident in our cases, and reference to Fig. 3 might suggest that there was a relation between the activity of the disease and the C.S.F. protein in Case 1 over the nine-year period of study. The C.S.F. protein in Case 2 has dropped from 400 mg./100 ml. in 1958 to 83 mg./100 ml. in 1966. Since 1964, a year after her hysterectomy, she has improved markedly and steadily. This is of interest as it might indicate that an alteration in hormone balance after hysterectomy may have favourably influenced the course of the disease.

The only biochemical abnormality consistently described so far in Refsum's syndrome is that of phytanic acid accumulation. While the C.S.F. phospholipid, lecithin, and globulin increases here recorded may simply reflect this abnormality, abnormalities of copper metabolism in the condition have been reported by several workers (Richterich *et al.*, 1965; Rake and Saunders, 1966). In Case 1 and a sib with optic atrophy (II 6) the caeruloplasmin was raised (see Table). The significance of this finding is at present obscure.

Continued follow-up of patients with Refsum's syndrome, with phytanic acid estimations being compared to clinical state, would seem a fruitful field for study. While alteration in phytanic acid intake may well affect the disease process, there may be physiological factors influencing the metabolic pathways of phytanic acid breakdown which also affect the course of the disease. Such a hypothesis would fit the observations above regarding the effect of intercurrent illness and improvement in a woman after the child-bearing period.

Summary

The results are reported of a clinical and biochemical study of two sibs with Refsum's syndrome who have been studied over a period of nine years. Three generations of the family were investigated, and no significant evidence of biochemical abnormality was found in any of the unaffected members. The serum phytanic acid level was raised in both patients, and high levels of phytanic acid in cerebrospinal fluid were present in one.

Fluctuations in the severity of the condition are compared with C.S.F. protein levels, and possible explanations for this characteristic variation discussed.

Medical Memoranda

Perforated Duodenal Ulcer Presenting as Acute Respiratory Failure

Brit. med. J., 1967, 3, 779–780

Respiratory failure in patients with chronic bronchitis and emphysema is usually part of a generalized cerebral depression from hypoxia and hypercapnia. It may come on suddenly, however, as a result of bronchial blockage from plugs of inspissated secretions (Simpson, 1962). In the following case a generalized peritonitis induced acute respiratory failure in a severely emphysematous patient.

CASE REPORT

A man aged 48 was admitted to hospital with bronchopneumonia and congestive cardiac failure complicating his long-standing chronic bronchitis and emphysema. His blood gases at the time of this admission were: *p*H 7.35 units, $P\text{CO}_2$ 72.5 mm. Hg, base excess +8 mEq/l., standard bicarbonate 31 mEq/l., and $P\text{O}_2$ 79 mm Hg. Chest *x*-ray examination showed appreciable generalized emphysema with bullous formation affecting both left and right apical zones together with recent inflammatory shadowing at the left base. After a period of bed rest associated with diuretics, digoxin, and antibiotic therapy, he made a satisfactory recovery but was still considerably disabled by his emphysema. His blood gases on 19 April 1966—that is, the day before his discharge—showed an established ventilatory insufficiency as well as impaired alveolar-arterial gas exchange (see Table).

He was advised to stop smoking, as this was considered the only thing likely to delay progression of his emphysema.

On 6 May at 4.15 p.m. he was readmitted in acute respiratory failure with complete apnoea. Emergency treatment in the casualty department consisted of endotracheal intubation with positive-pressure oxygen respiration, intravenous infusion of 7.5% bicarbonate, and hydrocortisone also administered by the intravenous route. The *p*H on admission was 7. Treatment was continued in the intensive care unit, where the patient was put on an East-Radcliffe respirator. Two hours later his general condition improved and he regained consciousness. By this time he had received 1 litre of 7.5% bicarbonate and was on tetracycline 100 mg. intramuscularly six-hourly. Investigations produced the following results: P.C.V. 60%; Hb 128%; serum electrolytes—Na 137 mEq/l., K 4.7 mEq/l., Cl 81 mEq/l.; blood urea 83 mg./100 ml. The blood gases at 6.30 p.m. are shown in the Table.

He now complained of severe abdominal pain and was found to have a rigid and silent abdomen. A previous long-standing history of dyspepsia suggested the diagnosis of a perforated peptic ulcer. This was confirmed by the presence of free gas under the right diaphragm shown on an *x*-ray film of the abdomen.

At laparotomy a perforated anterior duodenal ulcer was found with established generalized peritonitis. The perforation was closed with three chromic catgut sutures and an omental patch. After toilet of the peritoneal cavity, it was drained by tubes in the right subphrenic space and in the pelvis. After a further 14 hours on the respirator he was transferred to an oxygen tent. Tracheostomy was decided against, as he was by this time breathing well and was able to cough satisfactorily.

Table Showing Blood Changes

Date	Time	Treatment	*p*H	P_{CO_2} (mm. Hg)	Base Excess (mEq/l.)	Standard bicarbonate (mEq/l.)	P_{O_2} (mm. Hg)
19/4/66			7·33	72·5	+8	31	58
6/5/66	4.15 p.m.		7·0				
6/5/66	6.30 „	E.R. respirator. Bicarb. 1 litre	7·42	65·0	+13		300
7/5/66	11 a.m.	O_2 tent	7·34	80·0	+10·5	33·0	56
8/5/66	12 noon	O_2 „	7·34	68·5	+6·0	29·0	53
9/5/66	4.00 p.m.	O_2 „	7·34	72·0	+8·5	31·0	58

The Table indicates the blood gases during the immediate postoperative days. The patient showed steady improvement, but on the sixteenth postoperative day had a complete dehiscence of his abdominal wound. This was resutured under general anaesthesia without complications affecting the respiratory system. Ten days later he developed Friedlander's pneumonia and despite all attempts at resuscitation he died on 3 June. Unfortunately a post-mortem examination was refused.

COMMENT

There are two main types of respiratory failure: (1) ventilatory failure in which the P_{CO_2} is increased, and (2) impaired alveolar-arterial gas exchange with decreased oxygen saturation but without hypercapnia (Fletcher, 1962). The most severe cases of respiratory failure are usually encountered in patients with advanced emphysema and bronchitis. These patients usually show a composite picture of both underventilation and impaired alveolar-arterial gas exchange.

The above patient had advanced chronic respiratory insufficiency and was relying on his diaphragmatic movements for his tidal exchange. The duodenal perforation with its attendant peritonitis "splinted" his diaphragm and thus precipitated an acute respiratory failure. On 9 May 1966, three days postoperatively, he was breathing spontaneously and his blood gases gave almost identical values to those carried out on 19 April—that is, the accepted normal for him (see Table).

A pronounced increase in arterial P_{CO_2} causes cerebral vasodilatation and increased intracranial pressure (Comroe *et al.*, 1962). It is possible that hypercapnia might have been a contributory cause towards the perforation of a duodenal ulcer in this case; the CO_2 engendered raised intracranial pressure, stimulating the vagus centre with consequent gastric hyperacidity. Also hypercapnia stimulates release of adrenaline from the adrenal medulla.

We would like to think Mr. J. Moroney, under whose care this patient was admitted, for permission to treat and publish this case.

Lupus-like Syndrome Induced by Procainamide

Brit. med. J., 1967, 3, 780–781

Many drugs have been associated with the onset of a syndrome resembling systemic lupus erythematosus. Among the drugs implicated are hydrallazine; sulphonamides; anticonvulsants of the phenytoin group, and troxidone; penicillin; phenylbutazone; tetracycline; streptomycin and isoniazid; griseofulvin; thiouracil derivatives; and procainamide.

Since the first description of a syndrome closely mimicking, if not identical with, systemic lupus erythematosus, and occurring after the administration of procainamide (Ladd, 1962), 13 cases have been reported—12 in patients receiving the drug for cardiac disease (Hahn, 1964; Colman and Sturgill, 1965; Kaplan *et al.*, 1965; Paine, 1965; Carabia and Fortney, 1965) and one in a patient with dystrophia myotonica (Prockop, 1966). All previous reports have appeared in the American literature.

CASE REPORT

A 50-year-old widow attended hospital in May 1965 with symptoms suggestive of angina of effort, and was subsequently found to be hypertensive, with a blood pressure of 260/150 mm. Hg. Investigation showed no cause for this, and a diagnosis of essential hypertension was made. She was initially treated with antihypertensive drugs, but these were withdrawn when she had a myocardial infarction. In September 1965 she developed paroxysmal ventricular tachycardia and was given quinidine sulphate, but because of a drug rash occurring within 24 hours this was replaced by procainamide 500 mg. q.i.d.

In January 1966 she was readmitted to hospital complaining of left-sided pleuritic pain of sudden onset. She had no cough, sputum, or haemoptysis. She had a pleural rub at the left costophrenic angle and signs of a small left-sided pleural effusion. Her pulse was in sinus rhythm and her blood pressure was 160/100 mm. Hg. E.S.R., blood picture, and blood urea were within normal limits. Serum aspartate aminotransferase and serum lactate dehydrogenase were also normal. *X*-ray examination showed a small pleural effusion at the left costophrenic angle and marked cardiac enlargement. Though there was no obvious source of emboli, an initial diagnosis of pulmonary embolism was made and anticoagulation was started. Procainamide was continued as prophylaxis against further cardiac arrhythmia.

Initially there was some improvement, but three weeks after admission the patient began to complain of severe pain in the small joints of both hands and in the muscles around the shoulder girdles. Subsequently she had a further episode of left-sided pleuritic pain, followed by pain and a pleural rub on the right side. *X*-ray examination showed an increase in the left-sided pleural effusion and the presence of fluid at the right base. The E.S.R. was 70 mm. in one hour and the serum gammaglobulin 1.5 g./100 ml. The most likely diagnosis was thought to be multiple pulmonary emboli, and the oral anticoagulants were supplemented by high doses of intravenous heparin. However, no clinical improvement was noted.

The possibility of a collagen disease—a procainamide-induced lupus syndrome—was then considered. Positive L.E.-cell preparations were found on several occasions, the L.E. latex fixation and Jones tests were positive, and the antinuclear factor was demonstrated.

Therefore the procainamide was withdrawn and replaced by propranolol 20 mg. q.i.d. The effect was dramatic. The myalgia and arthralgia subsided; the chest symptoms and signs abated, and *x*-ray examination showed a clear right lung field within one month, followed by a gradual resolution of the effusion on the left side; the E.S.R. fell to 10 mm. in the hour in two months; L.E.-cell preparations were negative after six weeks, and the antinuclear factor was negative five months later.

When seen in October 1966 the patient was well, and was able to do light housework and take mild exercise.

COMMENT

In the 14 cases reported previously, in which similar reactions occurred, procainamide was given in a dosage of 1–5 g. daily. Symptoms of the lupus syndrome appeared after three weeks to 22 months of therapy. The commonest manifestations were polyarthralgia (14 cases), positive L.E.-cell preparations (13 cases), pleuropulmonary symptoms (nine cases), and the presence of antinuclear factor (in all five cases examined). Our patient took 2 g. of procainamide daily for five months before the appearance of chest symptoms.

Apart from two cases that were followed for only seven or eight weeks after procainamide was stopped, all have shown complete recovery within two years. This may represent a difference from the similar syndrome precipitated by hydrallazine, in which hypergammaglobulinaemia or antinuclear factor antibodies were found five years after discontinuation of the drug and disappearance of symptoms (Alarçon-Segovia *et al.*, 1965). Recrudescence has been found to follow re-exposure to the drug, but it was not attempted in this case.

There is still much controversy surrounding the mechanism giving rise to this drug-induced syndrome. Some authors Alarçon-Segovia *et al.*, 1965; Lee *et al.*, 1966) feel that the drug unmasks a predisposition to develop lupus erythematosus. Studies in patients with the "hydrallazine syndrome" have shown that symptoms and signs possibly due to S.L.E. were present before the drug was given. Patients who at one time had developed clear-cut drug-induced S.L.E. have occasionally been observed to have apparently spontaneous recurrence of the disease years later. There is, however, as yet no case reported of spontaneous recurrence or chronic S.L.E. induced by procainamide.

There are two other possibilities. Firstly, the symptoms could be a manifestation of drug toxicity or hypersensitivity—that is, a lupus–drug reaction. In favour of this a case has been reported (Prockop, 1966) of a patient with established S.L.E. who received full doses of procainamide for 15 months for a myotonic illness with no exacerbations of S.L.E., though there were episodic symptoms long before and long after the period of drug administration. This may be evidence that the lupus-like drug reaction differs from the disease. Secondly, the appearance of S.L.E. during drug administration might be coincidental, but the increasing number of cases reported makes this unlikely.

A review of the cases would suggest that procainamide is used in circumstances—for example, atrial fibrillation, paroxysmal atrial tachycardia, ventricular ectopics—in America where other drugs would be the first choice in Britain. It was only because this patient, with recurrent ventricular tachycardia, was hypersensitive to quinidine that procainamide was used. It would seem that this drug should be prescribed on a long-term basis only when there is no less potentially harmful alternative.

We wish to express our thanks to Professor O. L. Wade for permission to publish this case, and for advice on the manuscript.

Hypoparathyroidism and Malabsorption

Brit. med. J., 1967, **3**, 781–782

The association of secondary hyperparathyroidism with osteomalacia caused by malabsorption has often been noted (Davies *et al.*, 1956). There also seems to be a connexion between hypoparathyroidism and the malabsorption syndrome.

Bennett *et al.* (1932), in describing 15 cases of "idiopathic steatorrhoea," suggested that five may have had secondary hypoparathyroidism, in view of the finding of a raised serum inorganic phosphorus level. Several cases of idiopathic hypoparathyroidism associated with malabsorption and generalized moniliasis have been described (Collins-Williams, 1950; Salvesen and Böe, 1953a; Clarkson *et al.*, 1960). A few other cases of idiopathic hypoparathyroidism coexisting with malabsorption alone have been documented in recent years (Lowe *et al.*, 1950; Case Records of Massachusetts General Hospital, 1954; MacGregor and Whitehead, 1954; Jackson *et al.*, 1956; Williams and Wood, 1959; Cochrane *et al.*, 1960; Taybi and Keele, 1962). In a case reported by Clarkson *et al.* (1960) a flat small-bowel mucosa was found on biopsy, and correction of the hypoparathyroid state converted to normal most of the demonstrated abnormalities of absorption.

CASE REPORT

An unmarried woman aged 58 was admitted to hospital for investigation of an iron-deficiency anaemia which had been present for nine months and had failed to respond to treatment. She gave a history of a "nervous breakdown" followed by depression at the age of 22. A year later she had noticed a progressive deterioration of vision, and was found to have bilateral cataract, one of which was successfully removed at operation.

Clinical examination revealed a pale, nervous woman, with finger-clubbing. A postmature cataract was present in the left eye. Neurological examination showed a positive Trousseau's sign, but a negative Chvostek's sign.

Investigations showed a serum calcium level of 5.7 mg./100 ml. and a serum inorganic phosphorus of 6.1 mg./100 ml. Alkaline phosphatase was within the normal range. The serum albumin and serum iron were low, but serum vitamin B_{12}, folic acid, and cholesterol were normal. Tests for faecal occult blood were consistently negative. Faecal fat collection showed a level of 15 g./day, but D-xylose excretion test gave an equivocal result. Radiology showed no bony change, and small-bowel meal and barium enema were normal. Electrocardiogram was also normal. Biopsy of the small-bowel mucosa by the peroral method, using the Crosby capsule (Crosby and Kugler, 1957), showed marked villous atrophy with inflammatory changes and epithelial degeneration. The phosphate excretion index (Nordin, 1962 ; Nordin and Smith, 1965) gave results consistent with hypoparathyroidism.

The patient was treated with calcium supplements and vitamin D_2. After three months the biochemistry was normal, and repeat biopsy of small-bowel mucosa showed minimal damage and a marked improvement from the previous appearances.

DISCUSSION

Hypoparathyroidism and malabsorption have been reported together in more cases than would reasonably be expected by chance. Jackson (1957) thought that the association was well enough documented to be regarded as a "syndrome." There is, however, a lack of uniformity in the principal features of the reported cases. In some the symptoms of malabsorption are dominant, and in others the features of hypoparathyroidism. In most cases the symptoms give no clear indication of the primary condition.

Several possible explanations for the association have been postulated. Salvesen and Böe (1953b) suggested that intestinal moniliasis may have been the cause in their case, and perhaps in others. This seems unlikely to account for more than a few instances. They also suggest that patients with malabsorption have a relative parathyroid insufficiency due to malabsorption of a substance necessary for the continuation of normal parathyroid activity. There is, however, no evidence favouring the existence of such a substance. Hypocalcaemia may occur with either hypoparathyroidism or malabsorption. The serum inorganic phosphorus is raised in the former, and normal or low in the latter, the depression being caused by compensatory overactivity of the parathyroid gland. There is no evidence that this overactivity will eventually lead to hypofunction of the gland, or any definite evidence that hypoparathyroidism causes intestinal dysfunction and malabsorption. In the present case, if malabsorption were the primary disorder, the serum inorganic phosphorus would be expected to be low, or within the normal range ; this would be so if the patient was responding normally to the low serum calcium level due to poor absorption. In fact, however, the level is high, as in most of the cases reported. This suggests that the hypoparathyroidism may be the primary abnormality in many of the reported cases.

In the present case there is abundant evidence favouring a long-standing hypoparathyroidism. The development of bilateral cataract so early in life, together with mental symptoms (Clark *et al.*, 1962 ; Denko and Kaelbling, 1962), suggests that the condition was present 35 years ago. It is also known that hypoparathyroidism, whatever the cause, may remain latent for many years (Bull and Dillihunt, 1965). It seems likely that this patient's malabsorption was not of very long standing, as the symptoms of anaemia and possibly other deficiencies would have occasioned her attendance at hospital earlier. In addition, the treatment given in an attempt to improve parathyroid function resulted in an improvement in absorptive capacity of the small bowel, together with considerable restoration towards normal of the mucosal appearances. For these reasons, and the high serum phosphorus level, there is a possibility that parathyroid hypofunction has caused damage to the mucosa of the small bowel. None of the cases reported in the literature are incompatible with this hypothesis. This patient may therefore fall into the secondary coeliac syndrome group postulated by Hindle and Creamer (1965a, 1965b). They found that 36% of patients with a flat jejunal mucosa had some associated disease in addition to the symptoms of malabsorption. The primary disease may have been present for many years before malabsorption developed. They found it impossible to differentiate between primary and secondary coeliac syndrome groups on the basis of the deficiencies present and in the response to treatment. In some cases the mucosal changes were reversible with treatment of the underlying disease.

A wide list of conditions have been described as being associated with malabsorption and a flat jejunal mucosa. These include carcinoma (Creamer, 1964), malignant lymphoma (Gough *et al.*, 1962), diabetes mellitus (Mailman, 1958 ; Ellenberg and Bookman, 1960 ; Vinnik *et al.*, 1962), ulcerative colitis (Goulston, 1964 ; Salem *et al.*, 1964), infectious hepatitis (Astaldi *et al.*, 1964), tuberculosis and sarcoidosis (Hindle and Creamer, 1965a, 1965b), hepatic cirrhosis (Salem *et al.*, 1964), uraemia and congestive cardiac failure (Lochry and Creamer, 1966), and the dermatoses (*Lancet*, 1965). Hypoparathyroidism may therefore be regarded as one more disease which can cause the secondary coeliac syndrome.

I wish to thank Dr. Hugh Conway for permission to report this case, and for the helpful criticism which he made on reading the manuscript.

Schizophrenia in a Male Pseudohermaphrodite

Brit. med. J., 1967, **3**, 783–784

There now exists a considerable literature concerning intersex states in humans. Money (1952), reviewing the literature and studying a personal series of cases, found only one case with coexistent schizophrenia. Subsequently a further patient in this group was also diagnosed as schizophrenic (Money, personal communication). No further cases seem to have been reported in the interim.

CASE REPORT

A man aged 44 was admitted to hospital for investigation in March 1964, his only complaint being of fatigue, which he felt was related to poisons circulating in his blood stream after an attack of " chorea " at the age of 14.

He stated that at birth he had been registered as a girl and had been reared as such until the age of 14, when he was admitted to the local mental hospital suffering from " chorea with mania." While in hospital it was decided that he was in fact male, and on discharge he was re-registered. He seemed to adjust to the change quite rapidly and believed that the event was only a " nine-days wonder " in his village.

He left school at 18 and studied engineering, qualified in 1945, and subsequently worked regularly until 1961, changing his job frequently but always for promotion.

He married in 1947 (his wife was aware of his anatomical abnormality as a result of premarital love play). In 1950 they adopted a son, and a second in 1958. In 1960 the family moved from Scotland to London and the patient claimed that his wife found it impossible to settle down. She left him in 1961, taking the elder boy with her, and since then he has had no contact with her. At that time he became interested in spiritualism and began to take instruction in mediumship.

In 1962 he had his first recognized psychotic breakdown, while on holiday in Northumberland. He was thought to be deluded and possibly hallucinated, and a diagnosis of schizophrenia was made. He was admitted to hospital and given electric convulsion therapy and chlorpromazine, recovering in six weeks. He returned to London, but did not resume his work. In September 1963 he again went on holiday and took his young son with him. They camped in the Wye Valley, but after a few days he found an empty cottage, which he broke into, and set up home. This led to his appearing before local magistrates and being placed on probation. His son was taken into care. While on probation he moved to Oxford, claiming that he had friends in the neighbourhood, though in fact he knew no one. He found himself a flat, but made no attempt to get work, and remained at home doing almost nothing for six months. This led to his probation officer asking for psychiatric opinion, and the patient's subsequent admission to hospital.

Family History.—Father aged 76, alive and well. Mother died at age 66, said to have had chronic heart disease. Brothers: one aged 46, married with one son with congenital absence of auditory pinna ; another aged 42, also registered as a girl, redesignated as male after medical examination when in the A.T.S. There was no family history of mental illness.

Mental State.—On admission he was pleasant and co-operative, with no mannerisms. He gave a coherent account of his life up to the previous two years, but he was vague about recent events, in contrast to the detailed account of the rest of his life. He did not show gross thought disorder at that time, but there was some flattening of affect. He denied having any special powers of healing as he had claimed on his previous admission, but expressed the idea that his fatigue was due to toxins which circulated in his blood and caused scratches to appear on his arms. These ideas had little affective loading, and sank into the background when he was told that his blood tests were normal. He did not seem to be hallucinated, but admitted hearing voices in the past. He was unable to recognize the voices or to state what they said to him. From the psychosexual aspect he stated that he always felt awkward as a girl and that he was " a big clumsy tomboy." He was glad to change his role, and claimed it was little problem for him. His sexual orientation had been exclusively heterosexual. He claimed that he and his wife achieved mutual satisfaction by digital manipulation. He thought the greatest problem resulting from his genital abnormality had been his inability to pass urine in a standing position.

Physical Examination.—He was of normal male build and appearance (Fig. 1), and on examination all systems were normal apart from the genitourinary tract. There was a reducible left inguinal hernia, and a mass which was thought to be a testicle passed freely through the inguinal ring. There was a backward-pointing phallus about 1 in. (2.5 cm.) long. The scrotum was unfused, giving the appearance of labia majora and minora. Posteriorly there was a dilated urethral orifice which permitted the passage of one finger to the depth of 1 in. (2.5 cm.) (Fig. 2). No prostatic tissue was palpable. By digital stimulation of the hypospadic

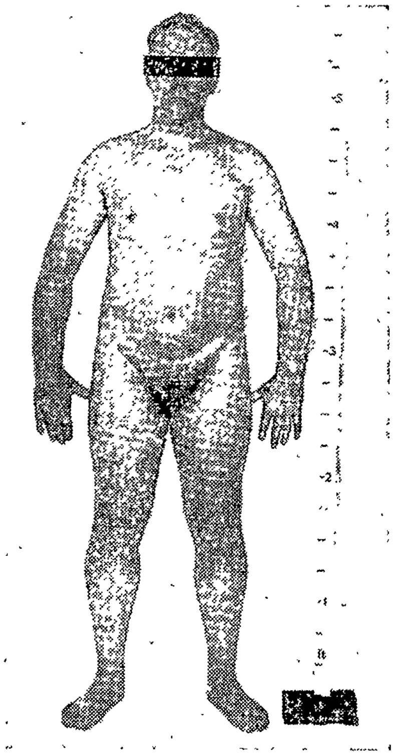

FIG. 1

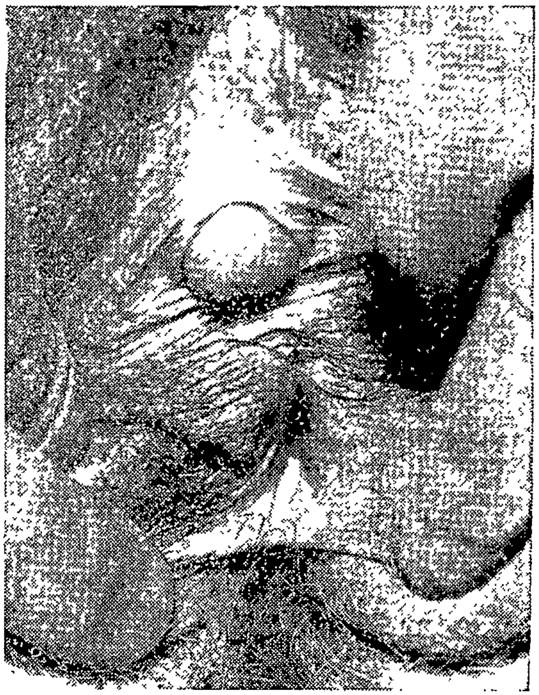

FIG. 2.—External genitalia showing phallus and external urinary meatus.

penis the patient was able to produce a few millilitres of fluid from this orifice. This fluid did not contain any spermatozoa.

Investigations.—Hb 96%; E.S.R. 2 mm. in one hour; Wassermann reaction and Kahn test negative; 17-ketosteroids 10.4 mg. in 24 hours; buccal smear showed no Barr bodies. I.V.P.: no suggestion of prostatic indentation of urethra.

Psychometry.—The Minnesota multiphasic personality inventory scales were within normal limits whether scored as a male or a female. The score on the Epstein test was within normal limits.

He was diagnosed as having schizophrenia and his physical state as one of cryptorchidism with a gross hypospadias. This was later confirmed at operation.

He was given no specific treatment, but after a few weeks he found himself a job with an engineering firm and left hospital, remaining in employment for 10 months. While in hospital he was referred for surgical opinion and subsequently had a series of operations; firstly, for repair of a left inguinal hernia, and, secondly, for a plastic operation to enable him to urinate in a standing position.

Since he left hospital he has shown more floridly schizophrenic symptoms. He believes that he is in communication with two people on Mars, and they are dictating a book on spiritualism to him. His communication with them is at times interrupted by other "spirit voices," which sometimes swear at him or pass insulting remarks. He is undertaking a process of "spiritual cleansing" which requires him to bath as often as possible, and he spends much of his spare time in the bath.

He does not speak of any of these ideas other than during psychiatric interview, but then it is difficult to interrupt the flow of his ideas. So far his delusions have not interfered with his work, though his employers describe him as slow and lacking in initiative. He feels extremely well and can see no reason for taking any form of medication.

His mental condition has remained unchanged since his plastic operation, but his mood has been one of mild elation since he was first referred for a surgical opinion, and he was grateful for the operation enabling him to urinate standing up. Until his admission he had never sought medical help for this problem.

COMMENT

Since Freud many analysts have stressed the aetiological importance in schizophrenia of patients' uncertainty about their sexual role. Organically orientated workers have also attempted to implicate gonadal malfunction in the aetiology of schizophrenia, but the weight of evidence suggests that such changes in structure or function as have been shown are either coincidental or the result of the disease (David, 1957).

Were either theory correct it would be anticipated that people with so marked abnormality of their sexual organs as to lead to incorrect sex assignment would have a high incidence of schizophrenia. In fact this association seems to be extremely rare.

I wish to thank Dr. B. M. Mandelbrote for permission to publish this case, and Professor G. Harris for permission to use the photographs, which were taken in the department of anatomy, University of Oxford.

Haemorrhage from Base of Tongue

Brit. med. J., 1967, 3, 784

When a patient presents with expectoration of blood its source is usually obvious. The history alone will often indicate the site of haemorrhage. We describe the case of a patient admitted to hospital with apparent haemoptysis who was found to be bleeding from the rupture of an enlarged vein at the base of the tongue. Enlarged, or varicose, veins have been noted in this area before, but little attention has been paid to them (Eggston and Wolff, 1947). It has been suspected that they could be the cause of bleeding, but we have been unable to find any previous description of a patient in whom this had actually been shown.

CASE REPORT

A man aged 58 was admitted to hospital after he had expectorated blood continuously for three days. During the previous week an exacerbation of his bronchitis had caused repeated coughing. On admission it was assumed that he had haemoptysis, but careful questioning suggested that the blood was coming from above the larynx. He had noted that he could produce heavily blood-stained saliva without coughing. There was no history of any abnormal bleeding.

General and oral examination showed nothing abnormal, apart from the presence of blood in the oropharynx. Chest *x*-ray picture, platelet count, and prothrombin time were normal, but the haemoglobin, which was 14.6 g./100 ml. on admission, fell to 9.6 g./100 ml. during the next five days.

Indirect laryngoscopy, performed the day after admission, showed an enlarged vein at the right side of the base of the tongue which extended over the anterior part of the epiglottis. There was a pool of blood around this vein. These findings were confirmed on examination under general anaesthesia, and it was then obvious that the haemorrhage was caused by a rupture of this vein in the glosso-epiglottic fold. Diathermy was applied to the bleeding-point and haemorrhage stopped completely. The patient returned home four days later.

COMMENT

Spontaneous haemorrhage from the throat is rare, but it must be considered when one of the usual causes of expectoration of blood cannot be found. If the site of haemorrhage is not visible on ordinary examination there should be no delay in using a laryngeal mirror to inspect the base of the tongue, hypopharynx, and larynx.

Our patient had a large vein at the base of the tongue, and it is probable that it had ruptured during a bout of coughing. It is stated that varicose veins in this area may occur in association with gout, cirrhosis of the liver, and influenza (Thomson and Negus, 1955), though no reason for this is given. In the above case the only associated condition was chronic bronchitis.

We wish to thank Dr. Maxwell Telling for permission to report this case and Mr. C. P. Mills for his advice and help.

Current Practice

TODAY'S DRUGS

With the help of expert contributors we publish below notes on a selection of drugs in current use.

Tolnaftate

Tolnaftate is marketed by Glaxo Laboratories Ltd. under the name Tinaderm.

Although the use of griseofulvin has revolutionized the treatment of some types of fungus infections of the skin and its appendages, there still remains a great need for a really efficient topical fungicide. Over the years a large number of preparations have been introduced, many of which have a potent in-vitro action, but in clinical practice they have been found to have little advantage over the other preparations, and indeed benzoic acid ointment *B.N.F.* is still one of the most commonly prescribed preparations.

Tolnaftate was synthesized by a group of Japanese workers[1] and has been used in the U.S.A. for the past four years; the clinical results seem promising.

Chemistry and Pharmacology

Tolnaftate is the approved name for 0-2-naphthyl *N*-methyl-m-tolylthiocarbamate. It is a colourless and odourless compound, soluble in organic solvents but almost insoluble in water. Most of the original clinical work was carried out with 1% solution in polyethylene glycol, but tolnaftate is now marketed as a 1% cream and 1% powder under the name of Tinaderm.

The in-vitro activity has been the subject of a number of reports.[2 3] The minimum inhibiting concentration in µg./ml. is between 0.08 and 0.008 for four common ringworm fungi, *Trichophyton mentagrophytes*, *T. verrucosum*, *Epidermophyton floccosum*, and *Microsporum canis*, and it is 3.0 for *T. rubrum*. There is no significant effect against *Candida albicans*, some species of aspergillus, or bacteria.

Massive doses in animals have shown no toxicity,[4] and Goldman and Lasser[5] could not demonstrate any adverse effects in seven patients treated for seven consecutive days with 1% tolnaftate lotion applied to 90% of the body surface. Rostenberg[6] was unable to sensitize 54 subjects, and the clinical reports do not mention cases where sensitization or a primary irritant effect has been noted.

Clinical Studies

Robinson and Raskin[7] treated 185 patients with superficial fungus infections and reported improvement in 173 after two to four weeks' treatment. This included 128 cases with *T. rubrum* infection, 124 of which were improved, but it is noted that cases with palmar and plantar lesions did not clear completely. Many other trials have been carried out, including those of Leer,[4] who described 520 patients with 73% showing clearing or improvement, Neuhauser,[8] who treated 100 patients with 86% clearing or improved, and Erve[9] reporting 176 cases, 25 of which had *T. rubrum* infection, and 23 of these showed a good response. Gould[10] treated 86 patients, including 40 in a double-blind study; twice as many sites cleared with tolnaftate cream as with the placebo. A double-blind technique was als used by Adam and Craig[11] on 29 patients, 82% of whon showed clearing or great improvement after three weeks' treatment.

Discussion

From all these reports it seems that tolnaftate is effective i the common ringworm fungus infection of the toes and groin and skin elsewhere. It has no worth-while action on nail ringworm and it is doubtful whether it helps much in scalp ringworm. The clinical results in tinea versicolor (*Malassezi furfur*) are good. It has no effect on *Candida albicans* infections, and this limitation will need stressing, as otherwise it wil be used in chronic paronychia and other conditions associate with this fungus. It would thus seem that many of the case where tolnaftate is most effective are those which usuall respond readily to the older fungicidal applications. However *T. rubrum* infections have often proved difficult to clear, an tolnaftate may well have an important place in their management, particularly in the toe-web and groin infections. Th widespread scaling of hands and feet which this fungus infection sometimes causes does not respond so readily, and Wethered Heeler, and Warin[12] in a double-blind paired comparison i such patients were unable to demonstrate any clinical or mycological effect after treatment with tolnaftate cream for on month. Another important aspect of management of fungu infection is the tendency to recurrence after treatment is discontinued. Erve[9] reports no recurrence during 10 months observation, but Robinson[3] mentions two cases which recurre after apparently successful treatment with tolnaftate. Th period of treatment required in each type of case is likely to b determined only when more experience of the drug has bee obtained. In most of the clinical reports two to four weeks treatment has been sufficient, but some conditions may wel require longer.

Dosage and Cost

Tolnaftate is available as Tinaderm in 1% powder 1% cream It should be applied once or twice a day.

The basic N.H.S. cost of 15 g. of cream is 3s. 9d. and of 50 g of powder is 4s. 6d.

ANY QUESTIONS?

We publish below a selection of questions and answers of general interest.

Phenylketonuria in Adults

Q.—*Is there any likelihood that the institution of dietary measures could improve mental defect in a young adult suffering from phenylketonuria who has had no previous treatment? Is the diagnosis of the disease in an older person made by the same tests as in infancy?*

A.—There is little likelihood that any worthwhile improvement in intelligence would result from giving a low phenylalanine diet to a young adult with phenylketonuria. Occasionally, however, treatment produces some improvement in behaviour or in epilepsy.

In affected females who become pregnant dietary treatment should be given throughout pregnancy to prevent damage to the foetal brain, which will result from the high level of phenylalanine in the foetal blood produced secondarily by the high level in the mother's blood.

The diagnosis of the disease in an older person is made by exactly the same tests as are used in infancy.

Diet and Hypochlorhydria

Q.—*Should patients with primary hypochlorhydria be given specific advice on diet, and, if so, what should it be?*

A.—Hypochlorhydria, if demonstrated by the augmented histamine test, implies that atrophic gastritis is present.[1] No specific diet or other treatment is indicated for this condition or for the accompanying failure of gastric acid secretion. However, atrophic gastritis and hypochlorhydria are associated with gastric ulcer,[2] gastric carcinoma,[3] and iron-deficiency anaemia.[4] Total gastric atrophy and achlorhydria are features of pernicious anaemia.

A barium meal examination and full blood count are advisable when hypochlorhydria has been demonstrated, and specific dietary or other treatment may be needed if any of these associated conditions are found.

Electric Toothbrushes

Q.—*What are the merits of electric toothbrushes?*

A.—It is to be expected that the rapid movements of the heads of electric toothbrushes would enable the teeth to be cleaned and the gingivae massaged more expeditiously, even when the heads are small. The use of a small head would enable the brushing to be more accurately controlled. Three types of brush movement are used in electrical toothbrushes. There is some evidence that an arcuate movement is less effective than plain horizontal or vertical movements in cleaning surfaces of teeth which are readily accessible.

Many clinical trials to evaluate the effectiveness of electrical toothbrushes have been undertaken. In general, they seem to indicate that electrical toothbrushes are equally as effective as conventional ones or may sometimes be more effective when the patient has not been given precise instructions on toothbrushing techniques.[1] In studies in which the electrical toothbrush has been used, after instruction, over a defined period of time sufficient for a conventional toothbrush to clean the teeth adequately—for example, three minutes—an electrical toothbrush is not usually more effective than a conventional one.

In brief, it would seem that the merits of electrical toothbrushes lie in their speed of action and possibly in more precise control. Children, aged about 5 and over, can usually handle them well after instruction and are attracted by their novelty. Many handicapped patients are able to clean their mouths more effectively than they would with a normal toothbrush.

Oedema with Disc Lesions

Q.—*I have observed oedema of the fingers in association with cervical disc protrusions and oedema of the foot with lumbar disc lesions. Have these observations been recorded, and what is the explanation? Is it possible for oedema of the contralateral foot to occur?*

A.—I am unaware of observations of oedema in cervical or lumbar disc lesions. I have not made this observation myself, though I have seen a very large number of patients with both conditions.

The only observation that I have made, and on only one occasion in a lumbar disc lesion, was a cyanotic, slightly swollen foot. This stemmed from the degree of paralysis below the knee which gave a problem similar to that of polio. In polio cyanosis and oedema occur from the lack of the "muscle pump," and that was the explanation in this patient. However, it would not be the explanation in most cases of lumbar disc lesion, and I would say never in the case of cervical disc lesions.

Headwear and Baldness

Q.—*Does tight, close-fitting headwear aggravate premature baldness in men or women?*

A.—The development of the common male-pattern baldness is dependent almost exclusively on hereditary factors and the degree of androgenic stimulation to which the hair follicles are subjected. Follicles are usually maximally stimulated in the adult male. The development of male-pattern alopecia in the female may be induced by normal female levels of androgen in those heavily predisposed genetically, but the incidence and severity are increased if androgen levels are raised.

For centuries tight close-fitting headwear has been blamed for aggravating male-pattern alopecia in both sexes, but there is no evidence whatever that it does so.

Notes and Comments

Gaucher's Disease and Pregnancy.—Dr. N. R. M. BUIST (Department of Pediatrics, University of Oregon Medical School, U.S.A.) writes: Your expert is in error in answering a question about the inheritance of Gaucher's disease ("Any Questions?" 8 July, p. 97). He states that a parent suffering from the recessive form of this disease has a 25% risk of producing an affected child. In fact the risk is much less. Since the incidence of autosomal recessive Gaucher's disease is not known, it is impossible to compute accurately the risks in this case. However, if one calculates the disease frequency of this form of Gaucher's disease to be 1/10,000, which is certainly an overestimate, then the heterozygote incidence is 1/50, and the chances of an affected homozygote producing an affected child would be 1/200. The figure of 25% chance of a child being affected is only applicable when both parents are known to be heterozygotes for a recessive condition.

OUR EXPERT replies: I was wrong not to point out that the incidence of 25% was to be expected only when both parents were heterozygotes for the recessive form of Gaucher's disease. As Dr. Buist points out, it is not possible to calculate the risks with any degree of accuracy in the case of one parent being a homozygote when the incidence of autosomal recessive Gaucher's disease is not known, but he is right to emphasize the decreased risk.

Tropical Ulcer.—Dr. J. N. MEIN (Milton, New Zealand) writes: Though I would agree that the regimen set out in the answer ("Any Questions?" 24 June, p. 818) is sound, it is probably impracticable and expensive in small, isolated hospitals, such as the one in Nigeria where I worked, and especially not appropriate for clinic use.

I found that a generous layer of B.I.P.P. (bismuth, iodoform, and paraffin paste) on gauze, covered with cotton-wool and a gauze bandage, could be applied even to a dirty ulcer and changed at weekly intervals, with no restrictions of activity apart from keeping the dressing as dry as possible. A large proportion of ulcers healed on this treatment, though larger ones certainly required a split skin graft. I found that I could get a good granulating area for grafting by using B.I.P.P. on an outpatient basis until the day before operation, then a few dressings of eusol or saline as the final preparation. I never used antibiotic cover postoperatively, and achieved a take-rate of about 80%. I avoided pinch grafts because of keloid formation at the donor site.

OUR EXPERT replies: I would agree with Dr. Mein's comments. He writes from personal experience in Nigeria. The treatment of tropical ulcers is bound to vary from area to area, depending essentially on funds available, the number of patients attending, as well as the number of medical attendants. Basic principles, however, remain esentially the same.

NEW APPLIANCES

Apparatus for Warming Blood for Transfusions

Dr. PATRICK J. BENNETT, senior registrar, the Middlesex Hospital, and London Chest Hospital, and Mr. F. ALLADINE, heart-lung machine technician, London Chest Hospital, write: The factors responsible for the harmful effects of rapidly transfused cold blood are now well recognized (Mollison, 1967). The blood is cold (4° C.) and acidotic ; it has an excess of disodium hydrogen citrate, which interferes with the ionization of serum calcium ; and it contains an excessively high serum potassium level.

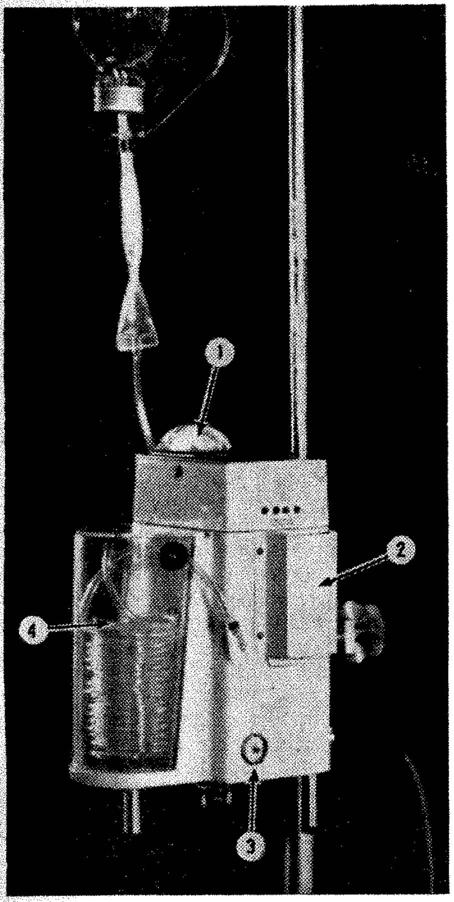

FIG. 1.—The apparatus.

There is evidence that the temperature of the transfused blood is an important factor in the morbidity associated with massive transfusion (Boyan and Howland, 1961). As the temperature of the heart approaches 30° C. there is an increasing risk of ventricular fibrillation, and it may be that the heart is more sensitive to the other factors—for example, raised potassium level of the transfused blood—as the temperature is lowered. Boyan (1964) reported a decrease in mortality from 58.3 to 6.8% using warmed blood in two matched series of patients receiving at least 3 l. of blood at a minimum rate of 50 ml./min.

Apparatus to warm blood has been described, but there has not been any general recognition of the part played by cold blood in operation mortality. Consequently, such apparatus has either been imported, with the result that its high cost has been a deterrent, or individual hospital departments have made their own.

It was decided, therefore, to construct a commercially available model in the hope of making transfusion of warm blood a reasonable prospect in other centres. It was designed with the object of economy in mind, and the simplest and cheapest method of warming blood is to add an extra length of tubing to the intravenous set, and place this in a water-bath maintained at 38° C.

Such an apparatus is of no value unless it is convenient to use. It was decided, therefore, that it should be compact enough to be attachable to a drip stand ; that blood should drip through readily without pumping ; and, ideally, that the extra tubing should be a " drop in " coil, ready at a moment's notice.

Description of Apparatus.—Simply, the apparatus is a 3-pint (1.7-l.) water-bath maintained at 38° C. by a 500-watt heater governed by a preset fine thermostat (Fig. 1, 1) which responds to a change of temperature in the water-bath of $\frac{1}{4}$° C. A second safety thermostat (Fig. 1, 2) automatically cuts off the electricity supply should the bath temperature rise above 40° C. for any reason. A small thermometer set in the base of the apparatus provides a final visual safeguard against overheating (Fig. 1, 3). The water is continuously circulated by a water-pump in the main housing to eliminate local temperature gradients. A 20-ft. (6.1-m.) coil of extension tubing fits into the small chamber at the front of the apparatus (Fig. 1, 4), made of perspex, to permit continuous observation. The unit weighs 11 lb. (5 kg.) and measures 12 by 7 by 7 in. (30 by 18 by 18 cm.).

Performance.—After switching on the apparatus takes about three minutes to achieve its operative temperature. Fig. 2 shows the temperature of blood leaving the blood-warmer at varying rates. It was felt that the performance with 1 pint (570 ml.) in five minutes was satisfactory, as this is generally acceptable as a level of rapid transfusion. It is possible to improve on these figures, but the additional length of tubing required impedes the free flow of the drip.

The apparatus has been in use for six months at both the Middlesex Hospital and the London Chest Hospital for warming blood in operations involving lung bypass, hypothermia, and arterial surgery. It has performed satisfactorily and has been found to be convenient enough to be used regularly by others, and no hazards have been uncovered.

Blood would take 30 minutes or so to traverse the heating coil at a transfusion rate of 1 pint (570 ml.) in four hours—a situation unlikely to occur when warming the blood as indicated, and, though there is evidence that blood may be incubated under sterile conditions for up to four hours without harmful effect on the red blood cells (Jandl and Tomlinson, 1958), it would seem both unwise and pointless to use any blood-warming apparatus except when transfusion is likely to be rapid.

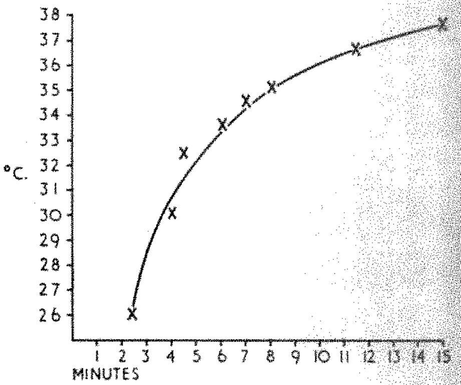

FIG. 2.—Temperature of 1 pint (570 ml.) of blood leaving the unit against time to pass through apparatus.

At present the extension tubing, sterilized by gamma-irradiation, is supplied as a loose coil in a plastic pack and has to be hand-wound to fit the apparatus. It is expected in the near future to have " drop in " coils prepared commercially in individual sterile packs ready for instant use in this unit.

We are indebted to Dr. H. Churchill Davidson, of St. Thomas's Hospital, for his advice on this project, and to the photographic department, the Middlesex Hospital, for the photograph.

The apparatus was manufactured by the South East Engineering Co., 93 Victoria Road, Romford, Essex, from whom these units and extension tubes can be obtained.

Book Reviews

Science and the Drinker/Driver

Alcohol and Traffic Safety. Proceedings of the Fourth International Conference on Alcohol and Traffic Safety. (Pp. 353+xiii. $10.00.) Bloomington, Indiana: Department of Police Administration, Indiana University. 1966.

The fourth international conference on alcohol and traffic safety was held in Indiana in December 1965, but the proceedings have only recently become available. They run to fifty papers contributed by specialists from many countries. Together they declare an academic insistence on comprehensiveness and on the value of knowledge for its own sake. Yet it can also be said that this material could conveniently be offered as a series of short books written for different specialists—sociologists, pharmacologists, clinical pathologists, psychiatrists, lawyers, and criminologists—such are the consequences of man's discovery of alcohol and what he regards as its desirable effects.

In the hands of such a team of specialists there is scarcely any limit to the permutations that can be devised with alcohol as one factor and human behaviour as the other; and the sponsors of this conference evidently agreed to the relevance of "Alcohol Effect on Latency of Caloric Nystagmus," "Biochemical Investigation of the Enzymatic Metabolism of Ethanol-Acetaldehyde in the Brain Cortical Substance," and "the Influence of Glucocorticoid on the Rate of Disappearance of Ethanol from the Blood of the Dog." These academic exercises at the periphery of the subject will doubtless attract the applause that is due to diligence and erudition; but the concern of the general public (activated by horse-sense rather than esoteric niceties) over the growing menace of road traffic, inevitably shifts attention to the man at the wheel.

Amidst a welter of scientific literature there is a danger that the stark realities of the situation may become obscure. The adverse effects of alcohol on behaviour and dexterity have been recognized for thousands of years. The danger of travelling at high speeds on congested roads is increasingly apparent, and it is perfectly plain that the hazards must be increased by the presence of intoxicated drivers. These generalizations have been confirmed so often by elegant and elaborate surveys that—in Dr. Ira Cisin's words: "We might almost say, 'Hold, enough. Do we really need further convincing on this point?'" Nevertheless, as Dr. Cisin points out, within this situation there are matters that call for closer definition and action. There is a whole range of degrees of "being under the influence of alcohol"; there are wide variations in the demands made upon the judgement of the motorist—drunk or sober; and there is the disconcerting observation "that people with a little alcohol in them are relatively lower risks than the people with no alcohol at all" (p. 51).

The last of these statements—far from justifying smugness among self-styled "moderate drinkers"—may in fact have little relevance to the problems inherent in drinking. The relatively poor record of the total abstainers may be due to the presence in this company of many good folk who suffer from mild obsessional disorders which tend to impair their skill and judgement when driving. In other words, the claim that a little of what you fancy does you good must be reviewed in the light of experiments where the individual acts as his own control (that is, with and then without alcohol) and not by comparison with people of a very different psychological make-up.

Dr. Cisin emphasizes the distinction to be made between social drinkers and problem drinkers—a matter to which Dr. Howard Pyle (President of the National Safety Council) also refers (p. 330) in his address at the Banquet Meeting. There appear to be three main types of drinker/drivers.

". . . the problem of the alcoholic," says Dr. Cisin, "is *not* that he drives after drinking excessively but that he does everything after drinking excessively, and our target with the chronic alcoholic is not to get him to stop driving after drinking but to get him to stop or control his drinking. Driving is only one of the things he does badly, and our objective is to treat his disease, alcoholism, on the safe presumption that, if we succeed, the driving will take care of itself."

The sociopathic driver who happens to drink; ". . . the man who characteristically goes through the school zones at fifty miles an hour . . . a destructive menace primarily because of his driving . . . His problem is not that he drives after drinking but the fact that he is permitted to drive at all.

". . . people who drink normally and who drive normally, but who on certain occasions find themselves in a position where the two acts are performed in temporal juxtaposition. . . . this group of normal persons is the group at which our propaganda must be aimed."

Even if we define the problem in this way, what are the chances of success in reducing the hazard created by the intoxicated driver? Dr. John Birrell, who is police surgeon at Melbourne, Australia, says: ". . . the sociologists have found that very few people are influenced toward change in behaviour by what they read in newspapers or see on television. People are influenced most by the standards of the groups to which they belong; within these groups are what the research people call 'opinion leaders,' whose influence on the attitudes and habits of their friends is quite decisive. . . . So probably we haven't got a public at all; we have a number of publics with quite different needs. We must do much more talking with community groups, no matter how small they are, because we then influence the influentials among them in their attitudes and often unconscious efforts on our behalf."

Incidentally, among a large number of excellent papers in the proceedings, Dr. Birrell's on public education and mass communication aspects is outstanding in revealing his insight into the specific problem and into human nature. He is surely right to urge the conference to "take up your pens and write for the layman and for the schools, for the schools particularly." Dr. Birrell's paper is itself worth ten dollars for its entertainment value. He writes with such gusto and humour that he is obviously the man to prepare a pamphlet on the subject of the drinker/driver which might be issued to every boy and girl when 15 years of age in the schools of the British Commonwealth.

STANLEY ALSTEAD.

Frontiers of Medicine

Lectures in Medicine. By C. W. H. Havard, M.A., D.M.(Oxon), M.R.C.P.(Lond.). (Pp. 381+xiii; illustrated. 63s. Paper 40s.) London: Staples. 1967.

I would like to have written this book. It is the kind of book for which any physician interested in explaining the frontiers of medicine would be proud to claim credit. It consists of a series of lectures to medical students in their final year on subjects which are of current interest to the practising physician but which are difficult to come by in the standard texts.

The topics discussed are inborn errors of metabolism (with a commendably broad classification), chromosomal abnormalities, evaluation of new drugs (containing some sensible words on clinical trials), corticosteroids, drug-induced disease, autoimmunity, cardiac arrest, respiratory failure, malabsorption, potassium depletion, and radioisotopes. A lecture on psychosomatic disorders seems at first sight out of place among so many recent advances in scientific knowledge, but it is as well that students are reminded that the majority of patients suffer from symptoms which cannot be adequately quantitated and yet require careful assessment if they are to be properly managed. The last three chapters are written by distinguished colleagues—viruses and disease (J. E. Stark), statistics (M. P. Curwen), and computers (L. C. Payne).

The exposition is clear and authoritative, at the same time avoiding dogmatism, and there are frequent summaries throughout the chapters. There is a selected bibliography for further reading, but this does not include the lecture on computers, an omission that needs remedying. The book is attractively produced and printed. Although primarily intended for medical students, I can think of others who would benefit from reading these lectures—for example, that relatively new educational phenomenon, the post-registration nurse. And it should not be despised by the postgraduate doctors who qualified when many of these subjects were being developed, for, as Payne says, " Human memory is like a vapour trail ; it attenuates with time."

Uveal Tract Disease

System of Ophthalmology. Vol. 9. Diseases of the Uveal Tract. By Sir Stewart Duke-Elder, G.C.V.O., F.R.S., and Edward S. Perkins, Ph.D., M.D., F.R.C.S. (Pp. 978 +xvi ; illustrated. £11.) London : Henry Kimpton. 1966.

Volume 9, the sixth of the 15 volumes of this monumental work covering the whole field of ophthalmology, has now become available, and, like its predecessors and no doubt its successors, is a truly remarkable achievement. Professor E. S. Perkins has co-operated with Sir Stewart Duke-Elder in the compilation of the seven chapters covering diseases of the uveal tract, and to anyone unconnected with the specialty it may well seem incredible that nearly 1,000 pages are required for adequate coverage of the text and illustrations of the various diseases which can involve the middle layer of such a comparatively small, though very important, organ as the eye.

In the middle years of the twentieth century there has been much research and discussion on the problems of uveitis, which used to be responsible, either directly or indirectly by causing cataract or glaucoma, for perhaps most of the blindness during the years between childhood and old age. Though the causes of some varieties such as syphilis, leprosy, and tuberculosis are proved, the origin of others, including the common serous and comparatively mild ones, are still mysterious. In days gone by tuberculosis or a septic focus far from the eye were thought without much evidence to be the factors precipitating an inflammatory reaction in the uveal tract, but now other possibilities such as allergy and autoimmunity are more often invoked. Since the aetiology so often remains obscure, therapy must be to a great extent empirical. But though we still cannot claim to be able to treat the cause in every case research has now provided us with a weapon which at least subdues the inflammation and controls the exudation which is so damaging to a complex optical organ, much of which is composed of central nervous tissues in which damage is incapable of repair. The advent of corticosteroid preparations for focal or systemic application has provided a therapeutic weapon for which the older ophthalmologists must have longed and which has completely altered the outlook for intraocular inflammations. Though corticosteroids have their dangers and do not actually cure the disease, they do at least protect the delicate ocular tissues until the inflammatory stage is passed.

The authors have, so far as possible, confined their attention to diseases of the uveal tract, though not forgetting that these may have a profound effect on other ocular structures, including the retina. Various chapters deal in great detail with circulatory disturbances, inflammations, degenerations, cysts and tumours, and the uveal manifestations of systemic diseases. The text is admirably comprehensive and written in excellent English. The illustrations, though possibly less copious than in some other volumes, are adequate and of high quality.

A work of this size must necessarily be mainly a reference book, and as such it succeeds in its object. It is an essential component of any ophthalmic library and of outstanding value to any English-speaking ophthalmologist.

Harold Ridley.

Cardiac Pathology

Cardiac Pathology. By Robert Lannigan, M.D., M.C.Path. (Pp. 385+vii ; 226 illustrations. £5 16s.) London : Butterworth. 1966.

This excellent, comprehensive book bridges the gap that has existed between the usual single chapter devoted to cardiovascular pathology in the student textbooks and the extensive reference volumes which are available on the subject. It contains 14 chapters, of which 12 are by the author.

Throughout, one is aware that this text has been written by someone with knowledge and great personal experience. Emphasis has been laid intentionally on morphological aspects. Facts are stated briefly and concisely. The incidence of different lesions from the literature is reviewed and supplemented by the author's own figures. Theories on controversial subjects—for example, the " nature of the tissue changes in rheumatic heart disease " or the " nature of myxoma " —are presented with clarity, and the author gently guides the reader to the currently accepted view. One of the outstanding chapters is that on diseases of the coronary artery. It contains beautiful descriptions of early and late lesions of atherosclerosis, and the theories related to aetiology and pathogenesis have been skilfully condensed into a few pages. The handling of some of the rare diseases such as virus and rickettsial endocarditis, thrombotic thrombocytopenic purpura (Moschcowitz's syndrome), and indeed the whole chapter devoted to the heart in diffuse connective tissue diseases deserves special mention.

Naturally, a book of this size cannot deal with every subject in great detail, nor does the author claim to do so. The section on myocardial infarction is at first glance surprisingly brief, yet it manages to give the important facts, including some histochemical findings. The book does not deal only with morphological aspects, and there is a chapter by Dr. Paul Davidson on the physiological aspects of normal cardiac output and cardiac failure. The final chapter is on heart diseases in childhood, by Dr. A. H. Cameron. For a book of this size it is understandable that only the more common congenital abnormalities could be included, and the interested reader is referred to classical references on the various subjects.

The entire book is well endowed with references. Photographs are excellent and include many on electron-microscopy. It will be an excellent aid for the postgraduate student in pathology or medicine and also for the practising pathologist. The hope is expressed in the preface that the undergraduate will also find it useful, and I believe that he will.

E. G. J. Olsen.

Cytogenetics

Human Population Cytogenetics. By W. M. Court Brown. (Pp. 107+xii ; illustrated. 40s.) Amsterdam : North-Holland. 1967.

Dr. Court Brown and his colleagues of the M.R.C. Clinical Effects of Radiation Research Unit have done more than any other body of investigators to elucidate human population cytogenetics. Thus this book, based on a series of lectures given in the University of London in 1966, deserves the attention of everyone interested in the subject. A prerequisite is that the reader must start with a working knowledge. One must not believe the editor's preface that this particular volume conforms to type in the series, *Frontiers of Biology*, in providing something on a wide and non-specialized basis. The author is more correct in saying that human cytogenetics is essentially in a descriptive phase and he jumps in at the deep end to describe, without a glossary of the sophisticated jargon.

To your reviewer, who is no pundit in cytogenetics but a haematologist who has had to live with them for the last decade during the exponential growth phase of this particular aspect of the subject, there were no terminological problems. I had only admiration for the fascinating accounts of chromosome studies on the general population, the identity of the chromatin-positive male, the Y chromosome, and the structural heterozygosity of the autosomes. I was left wondering, however, from the short introduction on lymphocytes, whether the author was concerned more in painting a realistic picture than in striving for precision of brushwork. This may be a legacy from the original presentation as lectures.

John F. Loutit.

Gynaecology for Students

A Short Textbook of Gynaecology and Obstetrics. By G. D. Pinker, M.B., F.R.C.S.(Ed.), F.R.C.O.G., and D. W. T. Roberts, M.Chir., F.R.C.S., F.R.C.O.G. (Pp. 188+xii ; illustrated. 25s. Paper 16s.) London : English Universities Press. 1967.

One author is from St. Mary's Hospital and the other from St. George's. The students of both hospitals and elsewhere should be pleased with this short textbook, for it is well written and the few line drawings by Mr. Emanual Lee illustrate the text well.

The approach is from clinical practice, and therefore pathology, psychology, endocrinology, and detailed consideration of such subjects as chromosomal abnormalities are dealt with very briefly indeed. Within these obvious limitations imposed by the authors on themselves, and by the series of University Medical Texts of which this is one volume, the book can be recommended both as an introduction to obstetrics and gynaecology and as revision reading. It is to be hoped that no student will believe that there is enough here to see him through his final examinations without attendance diligently at clinical and pathological sessions. He will also need more than a nodding acquaintance with some larger textbook where the inevitable dogmatic statements required by the format of this book can be seen to need qualification and modification.

PHILIP RHODES.

Reviews on Neuroendocrinology

An Introduction to Clinical Neuroendocrinology. Edited by Eörs Bajusz. (Pp. 573+xv; illustrated. sFr./DM.115.) Basel and New York: S. Karger. 1967.

This book is a difficult one to review because it can scarcely be regarded as a coherent whole. The title is misleading in that it implies a carefully graded introduction to the principles of the subject, whereas the book consists in reality of a series of independent reviews and papers on a rather heterogeneous series of subjects. Too wide a field is included under the general heading. The term neuroendocrinology can be justified for experimental work done on the controlling functions of the hypothalamus and basal nuclei, but it can scarcely be justified for many clinical aspects reviewed here such as secondary amenorrhoea or cerebral vascular disease.

The book is in fact a series of 24 separate articles by a total of 34 authors. Works of multiple authorship always require strong editorial guidance if they are to achieve a homogeneous whole. Here there is evidence of weak editorial control and of inadequate subediting. The systems of references in the texts are not uniform, some being numbered, others not. A marked Continental influence persists in many of the sections, not only in the lines of thought but even in the style of English. The specific weight of urine is referred to, for example, and in one article only 38% of the references given are in English, and in another only 36%. Some reviews are thorough, such as the section on the histology of the hypothalamo-neurohypophyseal system, but others are too narrowly specialized like the section on the physiology and pathology of this system, which confines itself almost entirely to posterior pituitary hormones and to a thorough survey of the diagnosis and treatment of diabetes insipidus. A comprehensive review of what is known about anencephaly is followed by one on the electroencephalogram in thyroid deficiency.

Some contributions are clear and concise surveys such as those on endocrine function in anorexia nervosa, and on the effects of sex hormones on human sexual behaviour. Others are essentially accounts of personal researches such as the paper on the assay of urinary A.C.T.H., or that on the effects of emotional stimuli on catechol amine excretion in urine. These stimuli range from industrial and office stress to the viewing of horror and of pornographic films by both sexes, the latter films having been borrowed from the Swedish Public Prosecutor. I am among those who feel that original results should not be published in this way, but should be submitted to the orthodox scientific journals which employ a referee system.

There are many good articles in this book, and the final section is a review of progress in basic and clinical neuroendocrinology by the editor Bajusz himself. If this last section had been considerably expanded it could have made by itself a more logical and coherent book than the present very assorted series of articles included in the volume.

C. L. COPE.

Satisfaction in Work

A Fortunate Man. The Story of a Country Doctor. By John Berger. Photographs by Jean Mohr. (Pp. 158; illustrated. 30s.) London: Allen Lane, The Penguin Press. 1967.

This book is an interesting blend of speculative essay and subjective biography. Berger has chosen for his central character a country doctor with the fictitious name of John Sassall. The working life of Sassall is depicted clearly and skilfully while his private and family life remain to a large extent concealed. Most of the biographical data are presented pictorially and almost half the book consists of photographs of Sassall, his patients, and the area in which they live.

Sassall practises a high standard of medicine. He is responsible for the domiciliary care of all his patients and for the treatment of many of those who require admission to hospital. He attends most of the births and deaths that occur in his practice and is fully aware of the various relationships, both family and social, that exist among his patients. We are shown photographs of him aspirating a chest, manipulating a spine, and taking an E.C.G. We are informed that he reduces simple fractures and is prepared to devote an hour after supper to patients whom he thinks might benefit from psychotherapy. These are procedures normally undertaken by many country doctors, and it is not because he applies these basic skills that Berger considers him to be a particularly good doctor. His primary quality is described as an ability to meet the deep but unformulated expectation of the sick for a sense of fraternity. He does this by encouraging his patients to recognize aspects of themselves in their doctor.

The impression I receive is that Sassall is not a particularly happy or contented man. He is often restless and periodically becomes deeply depressed. He is epitomized by Berger as fortunate because he finds a basic purpose and meaning to life in the work he does. He has become an integrated member of the community in which he lives and has established a very definite, individual, and intimate relationship with his patients. It is concerning the nature and significance of this relationship that Berger likes to speculate and generalize. I find some of the basic premises offered by Berger unacceptable—for example, that a strong element of superstition is always evident in "practical" common sense—but many of his ideas are interesting and worth reading.

I enjoy most biographies, and this one conforms to the general rule. It is unusual in its choice of subject and form of presentation. The book has been issued as a hard-cover edition by the Penguin Press. Its format is pleasing and it can be read with ease in one evening.

W. D. REES.

Books Received

Review is not precluded by notice here of books recently received.

Atlas of Roentgenographic Measurement. 2nd edition. By Lee B. Lusted, M.D., and Theodore E. Keats, M.D. (Pp. 249; illustrated. 83s.) London: Lloyd-Luke. 1967.

Human Atheroma. With Particular Reference to Endocrine Aspects of Aetiology. By W. L. Ashton, M.B., M.R.C.P. (Pp. 82. 21s.) London: William Heinemann. 1967.

Mental Subnormality. Subnormality and Severe Subnormality. 3rd edition. By W. Alan Heaton-Ward, M.B., Ch.B., D.P.M. (Pp. 100. 8s. 6d.) Bristol: John Wright. 1967.

Second Thoughts. Selected Papers on Psychoanalysis. By W. R. Bion, D.S.O., B.A., M.R.C.S., L.R.C.P. (Pp. 173. 25s.) London: William Heinemann. 1967.

Accidents in the Home. By David Cargill. (Pp. 123. 18s. Paper 7s. 6d.) London: Hamish Hamilton. 1967.

Proceedings of the Seventh Canadian Cancer Research Conference, Honey Harbour, Ontario. (Pp. 432+vii; illustrated. £6.) Oxford: Pergamon. 1967.

Management of Emotional Disorders in Paediatric Practice. With a Focus on Techniques of Interviewing. By Jerome L. Schulman, M.D. (Pp. 307. 72s.) London: Lloyd-Luke. 1967.

How to Avoid a Coronary Thrombosis. By David Cargill. (Pp. 114; illustrated. 18s. Paper 7s. 6d.) London: Hamish Hamilton. 1967.

Food Disorders. Medical and Surgical Management. By Nicholas J. Giannestras, M.D. (Pp. 521; illustrated. £8 5s.) London: Henry Kimpton. 1967.

Surgery of Rheumatoid Arthritis. By Leonard Marmor, M.D., F.A.C.S. (Pp. 261; illustrated. £5 12s. 6d.) London: Henry Kimpton. 1967.

Respiratory Physiology. By N. Balfour Slonim, M.D., Ph.D., and John L. Chapin, Ph.D. (Pp. 199+xi; illustrated. 66s.) London: Henry Kimpton. 1967.

Gynecologic Pathology. By Frederick T. Kraus, M.D. (Pp. 504+ix; illustrated. £6 18s. 6d.) London: Henry Kimpton. 1967.

A Synopsis of Otolaryngology. 2nd edition. By John F. Simpson, F.R.C.S., Ian G. Robin, F.R.C.S., John C. Ballantyne, F.R.C.S., and John Groves, F.R.C.S. (Pp. 529+xv; illustrated. 52s. 6d.) Bristol: John Wright. 1967.

The Use of Lateral Thinking. By Edward de Bono. (Pp. 156; illustrated. 18s.) London: Jonathan Cape. 1967.

Practical Anaesthesia for Lung Surgery. By Ruth Mansfield and Richard Jenkins. (Pp. 193; illustrated. 50s.) London: Baillière, Tindall & Cassell. 1967.

Growth and Development of Children. 5th edition. By Ernest H. Watson, M.D., and George H. Lowrey, M.D. (Pp. 463; illustrated. 73s.) London: Lloyd-Luke. 1967.

Drug Responses in Man. Ciba Foundation Volume. Edited by Gordon Wolstenholme and Ruth Porter. (Pp. 257. 65s.) London: J. & A. Churchill. 1967.

Orthopaedic Care of Children with Myelomeningocele: a Modern Programme of Rehabilitation

E. H. STRACH,* M.CH.ORTH., F.R.C.S.

Brit. med. J., 1967, 3, 791–794

> "A niche of usefulness and self-respect exists for every man, however handicapped, but that niche must be found for him."
> —JOHN GALSWORTHY.

An ever-increasing number of children suffering from congenital paraplegia due to myelomeningocele are being referred to the orthopaedic surgeon for treatment of skeletal deformities and for rehabilitation. The management of these children is often so complex that it presents a veritable challenge to the orthopaedic surgeon. The aim of this paper is to show some of the problems he has to deal with and to suggest some lines of management.

This study is based on personal experience with 173 patients (98 male, 75 female) who were referred for orthopaedic treatment during the past 10 years. They represent, therefore, a selected group of cases, but they are a typical cross-section of cases seen in the orthopaedic department.

I must emphasize that the intensive programme of rehabilitation described here is not accepted by all workers in this field.

The ages of the patients at the time of review or at the time of death were: under 5 years, 104+10 deaths; 5–10 years, 45+1 death; 10–17 years, 12+1 death. The primary myelomeningocele operation was performed in the first 24 hours in 81; at 2 to 7 days in 44; at 8 days to 6 months in 24; and later in 11. The timing of the operation in two patients was unknown and in 11 cases operation was not performed.

Hydrocephalus was present in 130 cases (75%). Ventriculo-atrial shunt operation was performed in the first month of life in 54 children and at a later date in 65 children. Spontaneous arrest occurred in 11 cases.

Paralysis of the legs was severe in 89 children (above the twelfth dorsal segment), moderate in 43 (above the fifth lumbar segment), slight in 15 (at or below first sacral segment), and spastic in 8. Paralysis was not present in 18 children.

Urinary diversion was performed in 23 cases.

Size of the Problem.—There is no increase in the number of children born with this malformation. With modern initial treatment of the myelomeningocele and the hydrocephalus many more children survive than formerly. The incidence of myelomeningocele in the United Kingdom is 2.5 to 3 per 1,000 live births. It has been estimated that in England and Wales 2,500 children are born every year with this malformation. Fifty per cent. will reach the age of 5 and a quarter of these will have no handicap and three-quarters will have a physical or mental defect. Eighty-four per cent. of all survivors are mentally normal.

Early Management

This is usually carried out by the paediatric surgeon in a neonatal surgical unit. Ideally, the myelomeningocele should be closed within 24 hours of birth to prevent infection and to preserve neural tissue. The frequent occurrence of hydrocephalus can be controlled by ventriculo-atrial drainage by means of a Holter valve. There are complications, but it is important to realize that the control of hydrocephalus is successful and without complications in two-thirds of the cases.

Orthopaedic Treatment

The aim is towards achieving independence of the congenitally paralysed child, notably to enable it to stand and to walk. There are cases where this aim is unobtainable; where there is severe mental deficiency, rehabilitation will fail. It is interesting to note than only 8% of all reviewed cases showed a severe degree of mental deficiency. Another 8% showed a milder degree, and in some of these rehabilitation was successful and even improved the child's mental capacity. It seems that physical improvement gives rise to an increased mental performance. Other factors militating against a successful rehabilitation are lack of determination of parents, a large head, and obesity.

Early Orthopaedic Management

In the first few weeks of life the orthopaedic management will take second place to the treatment of the spinal defect and hydrocephalus. However, an assessment of the neurological lesion and deformities should be done on the day of birth and repeated during the first few weeks of life. Muscle charting of the neonate is not an easy matter and often only a rough estimate of the activity of muscle groups is possible. Electromyography has been used but so far has proved of only academic interest. With experience, muscle testing becomes easier. Sharrard (1964) has rightly pointed out that the normal neonate moves his limbs freely while awake, and failure to move the legs spontaneously indicates a severe degree of paralysis. It is important to differentiate between spontaneous and reflex movements. The latter occurs in the isolated cord syndrome below the level of the lesion and is quite a common occurrence.

The neurological lesion is often segmental, and paralytic deformities occur according to the level of the lesion. For example, if innervation is intact down to the fourth lumbar segment and absent below it, the hips will be flexed and adducted, the knees will be extended, and the feet dorsiflexed.

Besides paralytic deformities there may be concomitant truly congenital deformities such as hemivertebrae, rib abnormalities, severe club-feet, and congenital dislocation of the hip. In the earlier stages these deformities can be controlled by conservative means, such as repeated moulding, retentive strapping, and plaster slabs or splints. There is, of course, a danger of sores developing in these insensitive legs, but a well-padded plaster or splint can be applied with impunity.

---

* Consultant Orthopaedic Surgeon, St. Helens and Whiston Hospitals (Liverpool Regional Hospital Board).

Later Treatment

When the child reaches the age of 14 to 18 months the orthopaedic surgeon's efforts will be directed towards ambulation. It is important that ambulation should be started at an early age, for it is physiological for the walking and standing reflex patterns to develop at that time. There will be a limited reflex pattern if lower-limb innervation is deficient or absent, but at least compensatory reflex action will be allowed to develop in the upper limbs and trunk. Theoretically, all paraplegics should be able to walk in one way or another, provided their legs are adequately supported and they can use their upper limbs. This applies to congenital paraplegia as much as to adult traumatic paraplegia. In the former there is no previous experience in walking; on the other hand, trophic sores are not as prone to develop as in adults. Early ambulation reduces the subsequent incidence of coxa valga and of trophic ulcers.

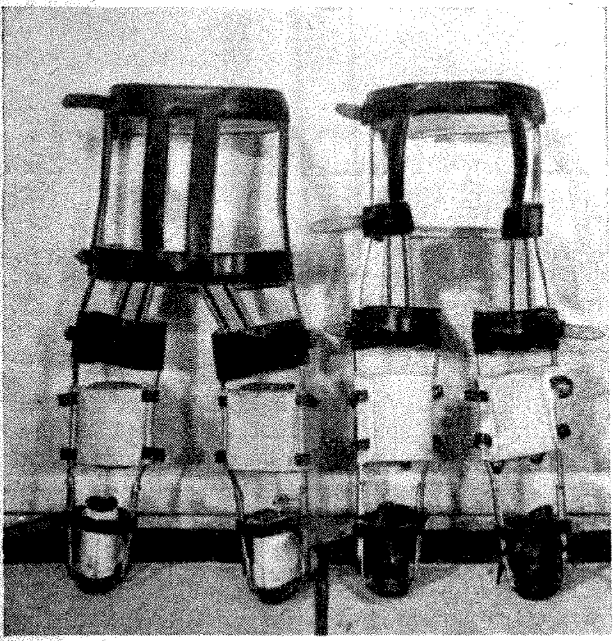

FIG. 1.—Two walking-appliances. The one on the right has a broad elastic sheet at the back to avoid pressure on any kyphosis.

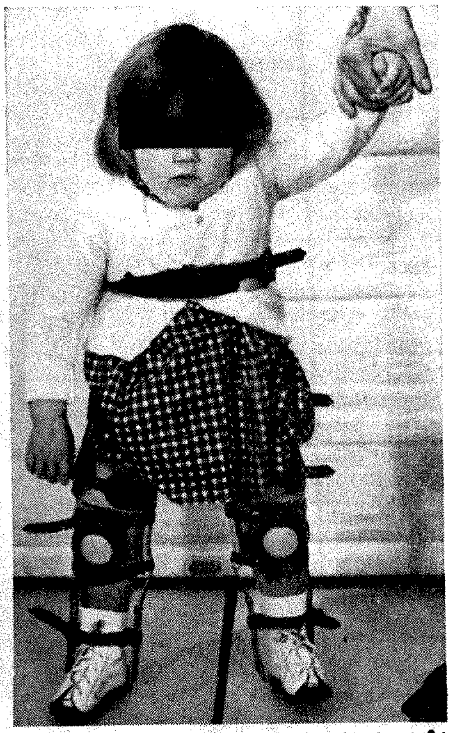

FIG. 2.—Complete paraplegia at the level of the eleventh dorsal segment in a child aged 3. Started to walk with the appliance at age of 15 months. Normally the trunk part of the appliance is hidden by her dress.

If there is complete and flaccid leg paralysis this task is simplified. There are no deformities, and all that is needed is to support the legs by an appliance which consists of two callipers joined to a body brace (Figs. 1 and 2). The children take to it readily and often protest when it is taken off. At first they are trained to stand in it for short periods. Additional support is given by holding their hands and allowing the children to grip so that they learn to use their hands purposefully for balancing and progression. They soon acquire a rocking type of gait. The appliance is worn for increasing periods during the day so that the skin can get used to the pressure. Sores are rare. The feet and any kyphosis are the areas at risk. It is useful to abduct the appliance at the level of the hips for several reasons. It gives a wider base and an increased side-to-side stability. It increases the excursion of the rocking movements during progression. If the hips tend to dislocate, the abducted position increases their stability. At times it was found useful to attach skis to the appliance, as this increases the front-to-back stability and gives the child confidence in the initial stages of walking.

As the child grows older a new appliance will have to be made, and this will contain hinges at the level of the hips to allow sitting. In some cases less rigid supports can be used as a lively splint in the form of a coil-spring appliance (Fig. 3). They allow the legs to swing at the hips. In all appliances a broad elastic strap passes over the buttocks to confer some extension to the hips. These straps may be extended to the heel in calf paralysis.

When the child is 5 knee hinges should be fitted to the appliance to allow more natural sitting, and, as the upper limbs become more efficient in balancing, the trunk part of the appliance can be replaced by a simple pelvic band.

Conventional callipers, the mainstay of the support in cases of poliomyelitis, are useless in spina bifida. They are used mainly for quadriceps paralysis, but in spina bifida isolated quadriceps paralysis is unknown. In a lesion at or above the second lumbar segment there will be quadriceps paralysis, but at the same time the glutei (which are innervated by the lower lumbar and sacral segments) will be paralysed, so that the calliper without a body brace will be insufficient. In a lesion at the fourth lumbar level the quadriceps will be working, so a calliper alone is unnecessary. The glutei will still be paralysed, and only a full appliance can replace the action of body support in these cases. Sharrard's posterior iliopsoas transfer is of immense value. It restores muscle balance around the hip and prevents dislocation, and if successful in restoring strong hip extension the child can keep the trunk upright and manage to walk without the full appliance.

Hip in Spina Bifida

(1) *Flexion deformity* is the most important hip deformity because it may severely hinder rehabilitation, thus making standing or walking impossible. It is caused by unequal muscle pull or by faulty posture. Most of these children attain a characteristic sitting posture with hips acutely flexed and externally rotated, with knees flexed, supporting themselves by the hands in front (Fig. 4). If they are allowed to sit like this while awake and to sleep on their sides with the hips bent, the flexion deformity will become fixed. It may yield to conserva-

tive treatment, but if present for a long time operative flexor release may be the only hope of enabling the child to stand upright. In this series flexion deformity was present in 25 hips of 16 children. Six hips required the flexor release operation.

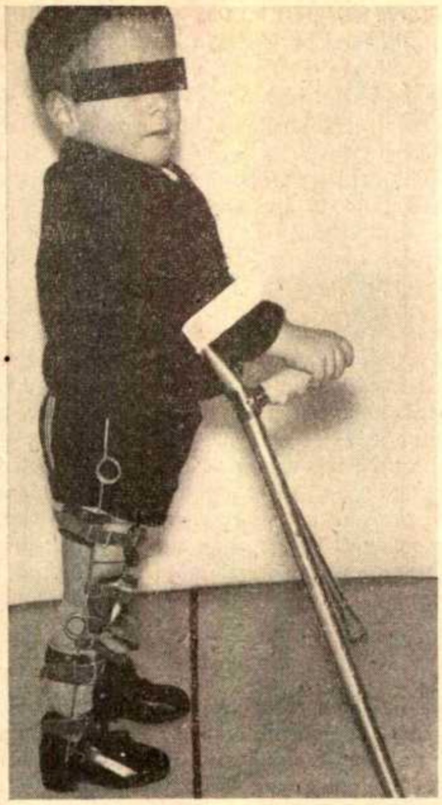

FIG. 3.—Child aged 4, with paralysis at third lumbar segment, using coil-spring appliance.

(2) *External rotation deformity* of the hips rarely interferes with ambulation and can be controlled by the appliance. Occasionally, one may have to transfer the sartorius to the outer side of the knee.

(3) *Abduction deformity* results from faulty sitting posture or from prolonged treatment of the dislocated hip, or it may be part and parcel of tightness of the tensor fasciae femoris. If postural it may respond to traction, but the tensor fasciae femoris was a potent cause of this deformity in 13 hips, and in five cases operative release was required. If associated with coxa valga it can be corrected by varus osteotomy.

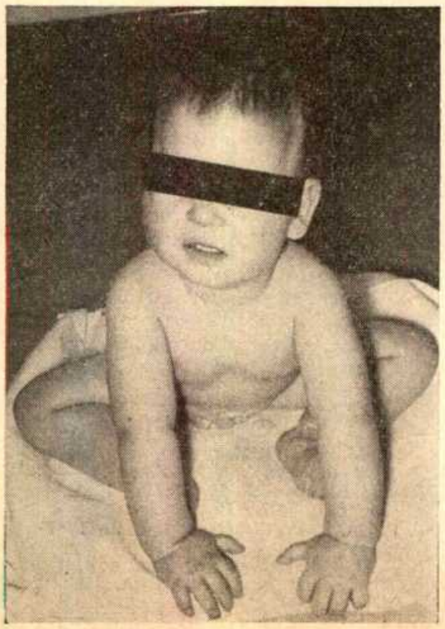

FIG. 4.—Typical sitting posture in severe congenital paraplegia (level ninth dorsal segment).

(4) *Dislocation of the hip* is common—103 dislocations or subluxations were found in 80 children (46% of all children were affected). There are four factors which can cause the dislocation:

(*a*) Laxity of the capsule is often present in any neonate but is much more pronounced if the hip muscles are paralysed. This factor was found in 24 cases.

(*b*) Unequal muscle pull is the most important single factor causing dislocation of the hip. In a lesion of the third or fourth lumbar segment the flexors and adductors are working while abductors and extensors are paralysed. The resulting adduction deformity leads to dislocation of the hip. In such cases the posterior iliopsoas transfer operation is the logical treatment of this muscle imbalance. It was present in 51 cases and in three cases of predominant spasticity.

(*c*) Coxa valga often occurs if the hip muscles are paralysed. It seems to be caused by the absence of the moulding force of the muscles and lack of weight-bearing. It predisposes to subluxation and later to a dislocation, which tends to occur in the slightly older child. It was present in 19 hips and in two cases with predominant spasticity.

(*d*) Severe dysplasia of the hip (Putti's embryonal dysplasia) was present in five cases. It was characterized by high dislocation present at birth and stiff hips, the picture resembling arthrogryposis. It was resistant to all forms of conservative treatment. In two cases open reduction of the hip was successful.

Treatment of Dislocated Hips

In the first few months a simple abduction splint, a modified Forrester-Brown splint, may be all that is required (Fig. 5). It was successful in 33 hips, though four of these were too recent to be sure about lasting success. In 28 hips dislocation recurred after such conservative treatment. In 29 cases adductor tenotomy was required. There were 16 psoas transfer operations ; nine of these also had a varus osteotomy (five of them at the time of the psoas transfer). All but one hip remained reduced, and in five cases of psoas transfer the full walking appliance was replaced by below-knee irons. Eighteen varus and rotation osteotomies were performed. Three open reductions were necessary.

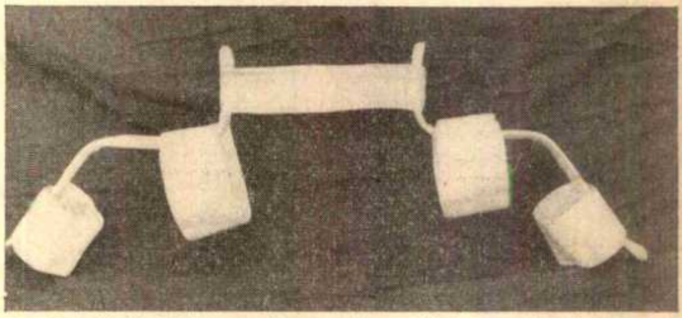

FIG. 5.—Modified Forrester-Brown splint. Vinyl-covered malleable steel bands. The connecting steel band lies in front of the abdomen, so that no pressure is exerted on the scar of the back. Velcro fasteners.

Foot Deformities in Spina Bifida

A deformity of one or both feet was present in 117 children. In addition, 25 had flail feet. The equinus element was present in 58 cases (91 feet), the calcaneus element in 54 cases (77 feet), the valgus element in 40 cases (58 feet), and the varus element in 35 cases (50 feet).

Most of the foot deformities were due to muscle imbalance, but the equinus deformity could not be explained by a segmental lesion. The equinus feet can result from spasticity or fibrosis of the calf, but in some cases it was due to an associated congenital club-foot deformity.

The conservative treatment should be started early, due care being taken to protect the skin. In cases of muscle imbalance correction of the foot deformities is easy, but relapse occurs readily; therefore a tendon transfer operation is required to restore muscle balance. This was done in 16 feet. Tendon transplants through the interosseous membrane were found particularly successful. There were four tibialis posterior transfers to the front and outer side of the foot for the varus deformity, and also six tibialis anterior transfers to the tendo achillis insertion for the common calcaneus deformity. Elongation of the tendo achillis was performed in 30 feet. In the severe congenital club-foot deformity a radical approach was adopted because weight-bearing on the deformed foot tended to cause pressure sores. A soft-tissue release was done on six feet, and wedge tarsectomy was performed in one " intrinsically vicious club-foot " at the age of 3.

If a child with only a mild paralysis develops an increasing varus deformity of the foot, or if the paralysis increases, one must suspect diastematomyelia. This happened in three children in this series. It was confirmed by myelograms, and the bony spur was removed, with arrest of the progressive paralysis.

Knee in Spina Bifida

The flexion deformity is important because it may hinder rehabilitation. It is not caused by muscle imbalance but by a faulty posture, spasticity, or fibrosis of the hamstrings. Conservative measures usually suffice, and up to 30° of flexion deformity can be compatible with ambulation if an appliance is to be worn. In other cases hamstring lengthening and preferably transfer to the patella was found satisfactory.

Genu recurvatum often occurs in lesions at the level of the fourth lumbar segment, when there is hamstring paralysis and a strong quadriceps. It can be prevented by splintage and does not interfere with walking. Elongation of the quadriceps was not found necessary.

Spinal Deformities

The scar overlying the myelomeningocele is usually quite healthy. There are often associated naevi or lipomata. In most cases the bony gap can be felt and frequently there is local kyphosis. This deformity makes the overlying skin or scar vulnerable to pressure and to avoid this the walking-appliance has to be fitted accordingly. Severe spinal deformities were present in 41 cases: 20 scoliosis, 11 kyphoscoliosis, and 10 kyphosis. Only conservative treatment was required, such as special braces and straps fitted to the walking-appliance. So far no spinal fusion or spinal osteotomies have been performed.

The lumbar lordosis was often combined with a flexion deformity of the hips and was relieved by the flexor-release operation of the hips. Any residual scar or swelling at the site of the myelomeningocele was protected by the lordosis.

Fractures in Spina Bifida

Fractures often occur in cases of myelomeningocele: they are often undetected, and they heal spontaneously with excess callus formation. They may be an incidental finding when an x-ray examination is carried out for some other reason. Prolonged plaster immobilization of paralysed legs causes profound demineralization of the skeleton, and this is often followed by fractures. Soon after removal of the plaster cast the affected limb swells, and this is usually the only clinical sign of a fracture. Both femora and tibiae can thus break after removal of a plaster spica, in spite of careful handling of the limbs. Such complications are rare after the use of splints; the little movements these splints permit seem to prevent the severe osteoporosis. Splints are therefore to be preferred to plaster, which should be kept on for the minimum possible time.

Epiphysial separations are less common, but have presented diagnostic difficulties. They may be mistaken for osteomyelitis or even bone sarcoma. The trauma is mild, an ill-fitting calliper may be the cause, bruising is absent, and there is no pain. The radiological signs may be unusual—widening of the epiphysial line, sclerosis, and debris in the soft tissues.

Treatment of fractures presented no problem; they healed readily, requiring protection by splints for only short periods. In this series 20 children had 36 fractures. One epiphysial separation healed slowly and with deformity.

Sores in Spina Bifida

Sores used to be a dreaded and almost inevitable complication in these cases. If insensitive skin is exposed to prolonged pressure, both from within (bony prominence) and from without (chair, bed, calliper, shoe), ischaemic necrosis will result, giving rise to the sore. Of all the factors operative in its formation, the time factor can be most readily altered. With active rehabilitation and early ambulation the endangered skin is exposed to pressure for short intervals. Sores are therefore not as common or as severe as in the bedridden or chair-fast child. In this series they were found at one time or another in 30 children.

Conclusion

An attempt has been made to elaborate the problems of the orthopaedic care and rehabilitation of this increasing group of congenitally paraplegic children. The question of schooling and training for employment is becoming acute. In the past the few educable survivors were absorbed into special schools, some entered ordinary schools, and many had no systematic education. At present there is a need for the speedy establishment of special schools for these children. The future may bring further advances in many fields, such as power-driven callipers, improved design of wheel-chairs, and electrical stimulation of the bladder. With all modern methods of treatment, of rehabilitation, and of education, it is hoped that many children will eventually be trained to be of some use in their homes and for some form of suitable employment. This may well bring self-respect and happiness to them and their families.

Summary

The orthopaedic problems of 173 cases of myelomeningocele are analysed. A plea is made for early ambulation with the help of a walking-appliance which is often successful even in the severest forms of paralysis. Such active treatment helps the physical and mental development of these children and often prevents complications such as fractures and sores.

My thanks are due to Mr. J. Atherton, of M. Masters & Sons Ltd., and Mr. S. Edney, of the Hamlin Surgical Appliances Co., for constructing the appliances and for many helpful suggestions; also to Mr. M. Bayliss for the photographic work.

Twenty-first World Medical Assembly

STANLEY S. B. GILDER, T.D., B.SC., M.B., B.S.

Brit. med. J., 1967, 3, 795–796

It may seem strange that the most significant item of business at a World Medical Assembly should be the definition of death, but this was the case in Madrid last week. The second item of significance lay at the other end of the spectrum of human life, with part of the scientific sessions devoted to a consideration of the population problems of the world from medical, demographic, ethical, and legal points of view.

Madrid exercises a civilizing influence on its guests, and perhaps this, as well as the steadying influence of the Secretary-General of the World Medical Association, Dr. ALBERTO Z. ROMUALDEZ, was responsible for the civilized manner in which the business of the Assembly was conducted during the week of 10–17 September. An international group of doctors from 32 countries, some with firm views on such matters as ethics or medical economics, is usually good for some display of temper, but in the whole week the only flutter in the Spanish dovecotes was during the scientific sessions, when the exhausted interpreters claimed a break after over four hours on population problems, at a time when about 80 Spanish doctors were clamouring to join in a heated debate which, all euphemisms aside, was concerned with the legitimacy or otherwise of the famous contraceptive pill.

British doctors will be glad to know that when the results of elections for vacant seats on the council of the W.M.A. were declared Dr. DEREK STEVENSON, Secretary of the B.M.A., topped the poll with 57, as against 54 votes for an Uruguayan and 50 for the editor of the *Medical Journal of Australia*, Dr. RONALD WINTON. Also elected was the former French member of council, Dr. J. JONCHÈRES, who has had a busy year in his practice in the cognac country preparing a document designed to show how to define death. Let us hasten to add that this does not mean that doctors are no longer sure when their patients are dead. The trouble arises, as everyone in the profession knows but the laity may not appreciate, because we can now maintain circulation and respiration artificially and there comes a time when the doctor needs to know two things—can he switch the machines off because the patient is in irreversible coma, and can he let his surgical colleagues remove organs for grafting? This has already been well discussed in various meetings, notably the Ciba Foundation symposium in *Ethics in Medical Progress*, at a French meeting on medical ethics in Paris in 1966, by a working group nominated by the Royal Medical Board in Sweden and headed by Professor GUNNAR BIÖRCK, by participants at the International Congress of Medical Law in Ghent last August, and no doubt on a thousand and one other less famous occasions. Obviously the crux of the matter is to prove "neurological death," and about this there is still much argument. For how long must the electroencephalogram be silent before one can assume that brain function has gone for ever? The figures given vary between five minutes and 48 hours, so there is little wonder that the W.M.A. was unable to solve the problem at once. They are keeping the subject under study and will give some guidance as soon as they can.

Medical Education

The medical education committee had started their planning for another world conference on medical education, for the W.M.A. believes that this subject is the concern of all practising doctors and not merely medical educators. After the last conference in New Delhi last November there was a movement by some educators to take the matter out of W.M.A. hands, but W.M.A. feels, perhaps with some justification, that a teacher is not going to admit that his methods are poor unless those he taught tell him so. The next conference will take place somewhere in Europe in 1972 and its theme will be "Medical Education: the Problem of Collective Responsibility." Mr. J. R. NICHOLSON-LAILEY, former Chairman of B.M.A. Council, has been active in promoting this. However, when his committee suggested that at this conference the views of medical students and of patients should be heard there was a horrified reaction from Continental colleagues who had never heard of Mrs. Helen Hodgson and her Patients' Association and felt that patients should be seen but not heard. Nevertheless, they agreed that the conference should give some thought to the interests of patients in their deliberations.

FIG. 1.—The new President of the World Medical Association, Dr. Alfonso de la Fuente (Spain), taking the presidential oath.

There was a time when discussion of medical economics and its allied problems (still quaintly termed "socio-medical affairs" in W.M.A.) took up a large part of the time allotted to business. Now for some unknown reason the situation has changed. This Assembly devoted very little time to this matter, the most interesting part of the debate concerning the attitude of the medical profession to unacceptable social legislation. The industrious Dr. R. SCHLOEGELL (Germany), who is the expert in this field, presented a paper on this, based on answers to questionaries from 26 national associations. Nine happy associations (including Sweden, Denmark, and Ireland) foresaw no trouble with their Governments over unacceptable legislation. The rest had adopted a variety of methods of protesting, but were unanimous in condemning the strike method used by other labour forces, though they found it legitimate to refuse to do their work under unacceptable conditions. In disputes between doctors and the Governments, the answers to the questionary indicated a certain measure of public sympathy for the doctors, provided of course that the public were not involved in any protest action the doctors took and that they believed the doctors were fighting for principles, not cash. Replies suggested that an important aspect of the problem was comprehensive information of the public and the doctors themselves about the issues at stake.

A matter which will come up for study in this committee next year is medical malpractice. Actions for negligence in the U.S.A. have multiplied beyond all reason, and this plague shows signs of spreading elsewhere. It deserves study on a world scale.

At the ceremonial session Dr. JESUS TAMESIS, of the Philippines, handed over the presidency of the Assembly to Dr. ALFONSO DE LA FUENTE, of Madrid, a thoracic surgeon, who will hold office until August 1968, when the next Assembly meets in Sydney and the office passes to an old friend and former Chairman of Council of W.M.A., Sir LEONARD MALLEN, of Adelaide.

Scientific Sessions

The general theme chosen by our Spanish colleagues for the Assembly was "Humanismo," a word not exactly equivalent to humanism, which has now come to mean a secular movement in the Anglo-Saxon world. Within this framework there were three meetings, if one includes the medical writers' conference—which really amounted to a discussion of pathology in art as exemplified in the works of Velazquez, El Greco, and Goya, all intensely concerned with the human condition of their time. The scientific sessions proper dealt with the population explosion, and with medicine and society.

Family Planning

As could have been predicted, discussion of the population explosion and family planning, which went on for hours beyond the allotted time, generated more heat than light, though two contributions were outstanding for their objectivity and quality. The first was by Professor J. **BOTELLA**, professor of gynaecology in Madrid, who discussed the action of the oral contraceptives with particular reference to his own work on their effects on ovaries, endometrium, tubes, cervical mucus, and cervical cytology. He explained that, whereas family planning was not allowed in Spain and the Catholic doctor could not prescribe the pills for this purpose, they found legitimate use as therapeutic agents, and all his studies on patients had been in such cases. (My own information is that sales in Spain, presumably for these purposes, have risen rapidly.) Professor Botella also pointed out that the mechanism of action was of great interest to a Catholic doctor. He said: "Putting aside the question of what Rome will decide, contraception through anovulation is not the same as contraception through such a mechanism as that of progestogens alone, which sterilize by (1) killing the morula by impeding its transport through the tube; (2) stopping the sperm from passing through the cervix." Thus it might be licit to use sequential or combined therapy but never progestogens alone, since these were really very early abortifacients. However, until the exact mode of action of oral contraceptives was known—and it was likely a multiple one, with variations according to the preparation used—no further opinions could be expressed.

Demographic Problems

This honest paper was followed by an equally honest summary of the demographic problem by Professor **DEL CAMPO**, who has the chair of sociology in Madrid. He pulled no punches in stating the case for urgent action to avoid impending widespread famine. For the first time, he said, *Homo sapiens* has to assume responsibility for the environment in which he lives. The problem must be faced; the only question is how to solve it, for birth rates depend on a complex of biological and social factors. A husband and wife may think that they determine how many children they will have, but in fact biology and society decide this for them.

When Professor Del Campo left the platform the theme took off into areas where a humble doctor is lost. Two theologians, recognized international authorities on the subject, Fathers **SIGMOND** and **ZALBA**, performed a series of intellectual acrobatics, but they did make some very valid points. They were anxious, for example, that family planning should never be used for political ends, to keep the powerful nations in power, or to raise living standards without reference to individual happiness. Father Zalba, having laid down a series of norms for use of oral contraceptives, as, for instance, to correct menstrual irregularities or to prevent ovulation in a woman whose health demanded postponement of pregnancy but whose husband would not co-operate, finally expressed the hope that "medical science would find a solution to the population problem more humane than the antiovulatory pill."

FIG. 2.—A general view of the Assembly at the opening session.

The Assembly a day previously had approved a resolution endorsing family planning in principle, though of course it could give no guidance on details.

The last major contribution to the debate on family planning in the scientific session came from a Spanish lawyer, and was chiefly notable for an unfortunate excursion into the fields of statistics and medical science, in which a certain amount of mythology replaced scientific fact. The following quotation is a good example: "Everyone knows that an organ which does not carry out its function is a sick organ, and that sexual excitation without fertilization is responsible for numerous disorders, just as are masturbation and the use of chemical spermaticides; even condoms affect male virility." All in all, contraception took a lot of punishment during the subsequent discussion, though two participants swam against the stream. An American Catholic physician said that if he had a dollar for every woman who had asked him for the pill he would be rich, and another doctor said bluntly that he preferred contraception to abortion, and these were the two alternatives. Unfortunately the Spanish press printed on Sunday, 17 September, under the heading "Conclusions of the XXI World Medical Assembly," without confirmation from either Council or the Secretariat, a report which may give the impression that W.M.A. is against the use of oral contraceptives. This of course is not so.

FIG. 3.—The platform party at the opening session. (From left to right) Dr. Stanley Gilder, Editor of the *World Medical Journal*; Miss Margaret Natwick (W.M.A. Headquarters Staff); Dr. Alberto Romualdez, Secretary General of the W.M.A.; (mainly hidden), Dr. Garcia Orcoyen, the Spanish Director General of Health; Dr. Jesus Tamesis, of the Philippines, the retiring President of the W.M.A.; Dr. Gerald Dorman (U.S.A.), Chairman of the W.M.A. Council; and Dr. Ernst Fromm (West Germany), Treasurer of the W.M.A.

Medicine and Society

With the second session on medicine and society peace returned. Drs. **DE LA QUINTANA** and **DE CALDAS** made sweeping historical surveys to demonstrate how the evolution of social thought and of social structures had affected the practice of medicine. The doctor may think he is free within the limits of contemporary medical science, but he is not; what he does and how he does it are very much conditioned by what society thinks about sickness and health (witness the contrast between the Greeks, who were against the treatment of persons with basic physical or mental defects, and the early Christians, who regarded suffering as ennobling) and by how society is structured. The third lecture in this session looked at the problem from another angle. Professor **LOPEZ IBOR**, a psychiatrist of international reputation, looked at the influence of the changes in modern society on the training of the medical student. He felt that we needed a new type of doctor, but we must make our educational experiments slowly, with pauses to assess the results. As a psychiatrist he was of course concerned about the tendency to dehumanize medicine and the need to counteract it.

It was altogether a useful week, and there were welcome signs that W.M.A. is gathering steam. People worked harder and played less, and most significant was the fact that for the first time in many years the Treasurer, Dr. E. **FROMM** (Germany), could come to the rostrum and announce that last year W.M.A. balanced its budget with a little to spare. Even the publications business is looking up, for next year both the Canadian Medical Association and the Australian Medical Association are going to distribute the *World Medical Journal* to all their members, while other associations are looking into the possibility of following suit. Once more also the *British Medical Journal* is taking an active part by preparing a supplement to the standard reference book *World Medical Periodicals*.

Correspondence

Letters to the Editor should not exceed 500 words.

Mortality of the Ambulance Ride

SIR,—Your recent correspondence on the mortality of the ambulance ride (26 August, p. 560, and 9 September, p. 678) calls attention to a problem which has been of considerable concern to ambulance authorities for a long time, although perhaps it has not received a great deal of mention in the medical press. Few doctors have much experience of travelling by ambulance.

In the first place the sensation when travelling as a passenger is quite different from that experienced when travelling as a recumbent patient, and the problem of suspension in ambulances is one which has received considerable attention, but there are difficulties. It may not be generally realized that there is no chassis which is designed specially for an ambulance. Ambulances in this country are built by a small number of specialist firms who have shown considerable ingenuity and are always willing to try new methods, but there is the limiting factor that all their work has as its foundation the commercially available types of chassis. The present position is to a large extent governed by economics, but this may not always be the case. The Ministry of Health Working Party on Ambulance Training and Equipment (the Millar Committee)[1] has drawn up an outline specification for a new chassis which may well be looked at by some of the manufacturers (Appendix I, part 2). For economic reasons, however, this specification may not be taken up unless the chassis can be put to some other commercial use as well. Perhaps the finest special-purpose ambulance was the Daimler ambulance which was available from 1949. In spite of its fine appearance and high quality it was a very expensive vehicle not only to purchase—and one must remember that the cost would be considerably higher today—but also to run, and in urban conditions it did not have a high degree of manœuvrability. An ambulance which may be entirely satisfactory in urban conditions may well prove to be unsuitable for work in country districts.

One of your correspondents suggests that there are medical reasons why the patient should face forward, and this is something which is worthy of further investigation. It is interesting to note that the most comfortable ride for any ambulance patient is in a railway train. Probably the main factor in making this so is that the ride is smooth and free from frequent starts and stops. It is sometimes difficult to persuade hospital doctors that their patients are more comfortable on long journeys in a train than in an ambulance, but the patients themselves and those in attendance upon them have no doubt that this is true.

In common with other branches of the Health Service the financial aspect is a considerable element in this problem, and consideration has to be given to how much money can be diverted with good reason for this purpose. Even when the suspension is improved, as, for instance, by special suspension of the actual stretcher within the vehicle so that in theory the patient has an extremely smooth ride, one is faced with another problem, and that is that in spite of all the evidence that the ride is very smooth some of the patients suffer from travel sickness, and these are people who do not normally suffer from this when in an upright position. Our experience is that, while these suspension units undoubtedly absorb vibration, the free movement inevitably causes more swaying. An interesting theory has been put forward that the body, accustomed as it is to adjusting itself when in an upright position while travelling, is unable to readjust itself during the comparatively short time that the patient is in the recumbent position.

Finally, ambulance crews are taught to study the comfort of their patients and to realize the risks of a rough ride. Stress is laid in their teaching on the fact that, while speed may be vital in reaching the ambulance victim, once immediate life-saving action has been taken there is seldom the same need for undue haste in reaching the hospital.—I am, etc.,

SIR,—I have always admired the French pragmatism in using well-sprung estate cars to move their invalids to hospital, while their dead go to the cemetery in a suitably ornate van. In England the comfort of the corpse merits a fine limousine, the medical needs of the severely sick a bone-shaker. The British ambulance, alias the French hearse, has brought some of our patients to the brink of the grave. May I join your previous correspondents (9 September, p. 678) in seeking a rapid research project to improve our devoted but antiquated ambulance service?—I am, etc.,

Derby. K. J. GURLING.

Thyrocalcitonin

SIR,—Your leading article on thyrocalcitonin (29 July, p. 256) mentions the discovery of the phosphaturic action of this hormone in the rat, which led Robinson *et al.*[1] to condemn the use of tests of parathyroid function based on phosphate excretion in man. Quite apart from the neglect of possible species differences, this conclusion is only partly justified. When a change in the secretion rate of parathyroid hormone occurs as a primary event, the thyrocalcitonin secretion would be expected to change in the same direction, and so to reinforce any change in phosphate excretion. This means, for example, that the diagnostic value of a normal test of phosphate excretion in excluding primary hyperparathyroidism has been strengthened.[2] On the other hand, when a change in the secretion rate of parathyroid hormone occurs as a secondary response to a change in plasma calcium from some other cause, thyrocalcitonin secretion would be expected to change in the opposite direction, and so to counteract any change in phosphate excretion. This is probably why the phosphate excretion index does not change in response to dietary calcium deprivation[3]; clearly the inference that this procedure does not stimulate the parathyroid glands[4] is invalid.—I am, etc.,

Place of the Mentally Retarded

SIR,—The very stimulating paper by Professor T. McKeown and Dr. I. Leck (2 September, p. 573) and also your leader (same issue, p. 567) prompt me to raise some points, necessarily limited by space. I work jointly for a local health authority and in a hospital for subnormals, and believe that the individual subnormal (and that is what this is, or should be, all about) requires a continuum in which he can be cared for. Therefore before moving 326 subnormal children from one camp (health) to another (education) I would like to be certain that they are going to benefit, and I find cold comfort in the fact that, according to the authors, 162 educationally subnormal children (13.6% of the total E.S.N. children in Birmingham) are already awaiting admission to school. What educational and training facilities would be available to the group the authors wish to transfer to district general hospitals? Clinical experience leaves me in no doubt that this group requires as much attention educationally as those the authors wish to transfer to the education authority.

The massive transfer of about half the hospital population to the local authority for residential care must be considered in more detail. Presumably these cases cannot go home, otherwise they would already be there. Suitable foster-homes for subnormals are notoriously difficult to find in any quantity. I presume, therefore, that the vast majority would be housed in hostels, and, as the Ministry of Health's standard sets a maximum of 25 beds per hostel, and there is no mention of any existing hostel accommodation in Birmingham, approximately 30 hostels will have to be found or built. When applied on a national basis it is in my opinion quite unrealistic to contemplate money, let alone staff, becoming available on this kind of scale. This is not to say that much more money is not required for the service; I agree completely with the authors that an inadequate service should not be disguised as desirable because it is economical.

One way of obtaining improvement in the service is to avoid multi-authority responsibility and duplication of effort; we should close our ranks, pool our resources, and integrate. A single responsible authority derived from health and welfare, education, and hospital authorities could well be the basic essential ingredient of such a concept. The best use is thereby, I suggest, more likely to be made of the available finances, staff, and accommodation, and the controlling authority would have a sense of unified responsibility and purpose.—I am, etc.,

Broomfield,
Chelmsford, Essex.
M. E. YORK-MOORE.

SIR,—I noted with some surprise in a leading article dealing with this subject (2 September, p. 567) the dogmatic statement that "clearly no special search should be made to 'ascertain' the large number [of persons with intelligence quotients of 70 or less] or to make special provision for them." If this is correct then much of the work of school medical officers and educational psychologists is indeed being misdirected.

The ascertainment of mental subnormality is essential to the assessment of the educational needs of the individual and his work potentials. It is equally important in the exclusion of emotional disturbance or physical handicap as a cause for apparent backwardness. Recognition of mental subnormality also makes it possible to avoid the placement of children in social or educational situations which they are intellectually incapable of surmounting, and which can give rise to severe psychic trauma to the individual concerned.

Finally, the lack of adequate provision for mentally subnormal persons may in part be due to past failures to ascertain the true extent of the problem of mental subnormality, and to plan suitably for the special educational, communal, and hospital care for all those in need of these facilities.—I am, etc.,

Rayleigh, Essex.

S.T.P. and Alcohol

SIR,—Your leading article (2 September, p. 570) ends with the admirable sentence, "Society has a responsibility to protect its members from drugs that can make them frankly insane or indeed kill them, as it has to stop the spread of communicable diseases." This certainly applies to marihuana.

However, the opposition of at least some psychiatrists to the prohibition of marihuana was intended to emphasize that the antics of a few hundred hippies was of trifling importance compared with the enormous damage to the health and happiness of the community caused by the current misuse of alcohol, which, after all, does in fact drive many people "insane or indeed kill them." In Scotland 20% of admissions to mental hospitals are now due to alcoholism, while W.H.O. lists alcoholism as the fourth most important cause of premature death. The number of chronic alcoholics in Great Britain is estimated at about 400,000.

Yet, so far from society feeling any responsibility for this, it allows the licensed trade to spend £23m. a year on advertisements designed to persuade families, especially teenagers and women, to drink not only more beer and wine but gin, whisky, and vodka; and the bizarre situation arises that the same newspaper might report a nine-month sentence on a purple-heart vendor and the elevation of a whisky vendor to the peerage. Yet it is known that the increase of alcohol consumed correlates with an increase of many social evils, including murders, suicides, divorces, road accidents, venereal diseases, and many other diseases such as tuberculosis, diabetes, and heart disease.

Reforms have been prevented to some extent because many believe that the only solution is prohibition, but that, as this is impossible, nothing more can be done. Recent studies, however, have indicated that social attitudes to drink are proportional to the degree of alcoholism in the community, and that much depends on the example of the medical profession.

Perhaps, therefore, we should reassess whether garish American bars are not out of place in medical premises, and whether young doctors, many of whom dislike drink, should not be offered soft drinks as well when offered alcohol. Also, are cocktails and liqueurs really necessary before and after medical dinners respectively? Or the announcement at 9.30 that the "bar is still open"? Is the argument that the sale of drinks is a gold mine for the society ethically sound, or should societies, like some Governments, refuse to benefit from such profits? Is there justification for the claim frequently made by the alcoholic that it is impossible to get on in England if you are a non-drinker? And is the propaganda image of the non-drinker as a dull, unsociable fellow really justified?—I am, etc.,

Sodium Uptake in Peritoneal Dialysis

SIR,—I wonder if Dr. J. D. Swales (5 August, p. 345) is doing himself an injustice in his apparent assumption that he failed to remove sodium from his patients by using hypertonic (6.36 g. dextrose/100 ml.) peritoneal dialysis fluid. The fall in sodium concentration which he observed when using this occurs always, even when the plasma sodium concentration equals or exceeds the initial level in the fluid, provided the observation is made during the first hour of the exchange. This is simply a reflection of the disparity of the osmotic and sodium gradients across the membrane. Dr. Swales did not mention the volume of fluid removed when the dialysate sodium concentration dropped to 123 and 122 mEq/l. (final Table), but if, as is likely, this corresponded to the volumes given in Fig. 4 (300–450 ml. for exchange) then the sodium balance referable to the patient would lie between +1.4 and −19.4 mEq per exchange. ([Vol. out × [Na] out]−[Vol. in × [Na] in].) That the postulated negative balance is the one that most likely obtains is apparent from the results shown in Fig. 4.

The significance of sodium balance during dehydrating peritoneal dialysis is of further importance when this form of treatment is applied to patients with fluid overload but relatively normal initial plasma sodium concentrations. We have observed[1] that the sodium concentration in the excess fluid removed (the above balance figure divided by the volume difference) ranges from 70 to 110 mEq/l. This means that even though the patients were in negative sodium balance they became hypernatraemic. Under these conditions we have observed plasma sodium concentrations as high as 168 mEq/l.

Like Dr. Swales, we have toyed with the idea of reducing the amount of sodium in the dialysate fluid, and Messrs. Allen & Hanbury have provided basic solutions for us with sodium concentrations as low as 115 mEq/l., with a corresponding adjustment of osmolality. This does make things complicated, and a satisfactory alternative is occasionally to substitute a litre of 5 g./100 ml. dextrose for one of the two units of peritoneal dialysis fluid. With a 45-minute equilibration period this will usually remove about 50 mEq of sodium, and is well tolerated by the patient. I cannot imagine, however, that even this would have benefited the patient who first drew the attention of Dr. Swales to the problem.—I am, etc.,

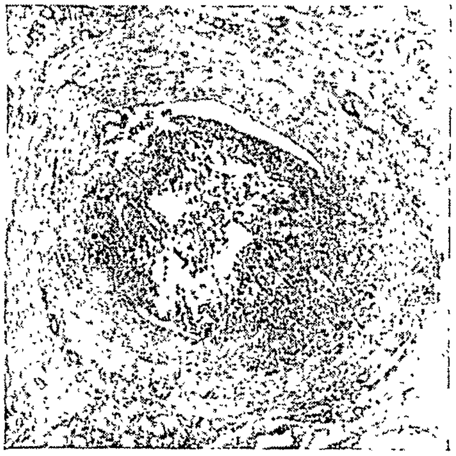
Peripheral Gangrene in Infancy and Childhood

SIR,—Referring to the correspondence "Peripheral Gangrene in Infancy and Childhood" (10 June, p. 700), I would like to add a few points to the discussion. Peripheral gangrene is also one of the intriguing problems in Kenya. Work on this condition has been done by J. R. M. Miller[1] and more recently by members of the Glasgow team of the Nairobi Medical School.

I had the opportunity to study the histopathological sections of tissues removed from a few of these patients. Invariably there was in these cases an infectious condition (pneumonia, gastroenteritis) antedating the onset of the usual symmetrical gangrene. The histopathological findings were controversial.

In a necropsy case no vascular lesions could be found in the arteries of the affected areas; vascular lesions were also excluded in another case. The histological sections of the other organs in the necropsy case revealed the presence of a "virus-infection." Unfortunately we could not identify the causative virus on the basis of the histopathological findings only (rickettsiosis? adenovirus infection?). Contrary to these findings a proliferative endovasculitis with secondary thrombosis was observed in two other cases (see Fig.). The histopathological lesions in those two cases resemble the morphology of a peripheral arteritis (vaguely resembling thromboangiitis obliterans) in young adult patients with an apparently identical condition. Identical observations of peripheral gangrene were also noticed in the course of an adenovirus infection.[2]



Proliferative endovasculitis. (H. and E. ×25.)

It appears to me that some of these cases with a peripheral gangrene of obscure origin may indeed be related to "infectious angiitis."[3] A. Th. Ariëns and B. E. Kingma[4] advocated the administration of prednisolone and antibiotics in such cases; these authors claimed to have obtained a dramatic improvement in one case after this form of treatment.—I am, etc.,

Activation Analysis

SIR,—Your leading article (26 August, p. 509) indicates that uniform irradiation of the thyroid gland is not possible with neutrons. In fact this is true only for irradiation by thermal neutrons as used in the technique being developed in France,[1] for which it is necessary to use an internal standard of radioactive iodine-129.

In reporting our measurements in man[2, 3] we have shown that by deliberately filtering out the thermal neutrons and using only neutrons of higher energies (epithermal and fast neutrons) not only is the irradiation adequately uniform but also the iodine in the gland is activated preferentially compared with sodium and chlorine, because of the behaviour of the neutron capture cross-sections of these elements as a function of neutron energy. Our own studies with thyroid phantoms of various sizes, and measurements by Fairchild,[4] confirm that uniformity of thyroid irradiation using epithermal and fast neutrons is to be expected. Good agreement has been obtained between in-vivo activation measurements, and subsequent in-vitro activation and chemical measurements of iodine in the same gland.[2 3]

Our reports have already shown that the in-vivo measurement of total intrathyroidal iodine in man can be made with radiation doses to the thyroid not exceeding those of an uptake test using 12 μCi of iodine-131.—We are, etc.,

Hypercalcaemia and Malignant Tumours

SIR,—The report of hypercalcaemia in yet another patient with a bronchial neoplasm (2 September, p. 590) was interesting because of the mental and neurological changes due to the hypercalcaemia. Removal of the tumour caused a fall of the plasma calcium to normal within hours. What was less interesting was the longish discussion on the mechanism of the rise in plasma calcium. The authors wrote that it was not possible to decide whether the tumour removed was producing a substance having the activity of parathyroid hormone or a "parathyrotropic" hormone.

In 1963 Liddle and his co-workers[1] demonstrated the presence of corticotrophin, or a closely related polypeptide, in the primary tumour and metastases from patients with greatly increased adrenal cortical activity in the presence of malignant disease. Other instances of ectopic hormone production by tumours have in recent years been reported fairly frequently, and in 1941 Albright[2] first suggested that tumours of nonparathyroid origin might produce a substance with biological activity similar to that of parathyroid hormone. Two recent studies,[3 4] the first using a bioassay and the second radioimmunoassay, have both shown the presence of parathyroid hormone-like material in nonparathyroid tumours from patients with hypercalcaemia but without bony metastases. Hyperplastic parathyroid glands have not been found in such patients, and in one patient (in whom primary hyperparathyroidism was excluded at post mortem) Sherwood and his colleagues[4] found an increased amount of parathyroid hormone in the blood which was in the hyperparathyroid range.

The correction of the hypercalcaemia within hours of the removal of the malignant tumour, the absence of skeletal metastases, the hypophosphataemia, the lack of hyperplastic parathyroid glands, and the results of assay of the tumours are evidence that some tumours in patients with malignant disease and hypercalcaemia produce a substance with activity like parathyroid hormone. There is no evidence for any "parathyrotropic" hormone in this syndrome, or for that matter in hyperparathyroidism (unless possibly sometimes growth hormone[5] and thyrocalcitonin might be included in this term).—I am, etc.,

Dietary Calcium and Hypercalciuria

SIR,—The article by Dr. M. Peacock and others (19 August, p. 469) rightly stresses the difficulties associated with the definition of hypercalciuria. However, we are unable to agree with their conclusion that "hypercalciuria can *only* be defined in relation to calcium intake." We have recently observed[1] a highly significant relationship between the urinary excretion of calcium and sodium in stone-forming patients, confirming similar findings by other workers.[2–4] On recalculation of our original data on the basis of mg. calcium/kg./day we find that our comparatively young stone-forming males constantly excrete more than 6 mg. calcium/kg./day on a diet containing approximately 10 mg. calcium/kg./day. These cases are compared with a small group of normal young males who constantly excrete less than 4 mg. calcium/kg./day on the same diet.

The Table shows the comparative values for urinary calcium excretion when both groups of subjects were given a low calcium diet containing not more than 2.6 mg./kg./day. In period A this diet contained less than 80 mEq sodium/day. In period B the same diet was supplemented by 85 mEq sodium/day, administered as sodium chloride.

These results show that there is a significant difference between the two groups in period A when calculated as mg. calcium/kg./day, and also the difference is highly significant when mean total calcium excretion is expressed in mg./24 hours, as it was in our paper. The addition of sodium in period B also reveals a highly significant difference in the increase in calcium excretion between the two groups. The urinary calcium excre-

Diet	Group	No. of Patients Studied	Mean Urinary Calcium mg./kg./day (±SD)	t	P
Period A. Low calcium diet ≯2·6 mg./kg./day	Hypercalciuric	14	2·61 (±0·6)	4·2	<0·001
	Normal	10	1·58 (±0·38)		
Period B. Low calcium diet plus 85 mEq sodium/24 hours	Hypercalciuric	14	4·1 (±0·9)	6·9	<0·001
	Normal	6	2·3 (±0·37)		

tion of the stone-formers now significantly exceeds their dietary intake over a five-day period. The normal controls showed much less increase in calcium excretion. The levels of urinary sodium were in the same range in both groups. This observation appears to indicate that there is a renal factor involved in the production of hypercalciuria in our stone-forming subjects.

We feel, therefore, that hypercalciuria cannot be defined solely in relation to calcium intake, and that sodium intake is an equally important factor. While it is well established that patients with "idiopathic hypercalciuria" absorb more dietary calcium than normal subjects, this may be a compensatory mechanism for increased urinary calcium excretion rather than the basic cause.—We are, etc.,

Oxygen Therapy

SIR,—Gratifying as it was to read Dr. I. D. Green's account (2 September, p. 593) of the performance of the modernized Tudor Edwards spectacles, it is essential to describe an important disadvantage.[1] Wearing the device does not preclude smoking. Small superficial burns round the nares after two or three quite exciting little conflagrations from this cause have been seen. Unfortunately, the consequences may not always be so limited.

Other experience[2] supports Dr. Green's finding that nasal catheters can be used successfully for "controlled oxygen therapy," but it also suggests that this illogical practice may be safely carried to its logical conclusion. Thus the most severely ill only get air to breathe with just as good a prognosis and a lot less trouble in management.—I am, etc.,

[1] Addis, G. J., *Lancet*, 1963, **1**, 1084.
[2] —— M.D. Thesis submitted to Glasgow University, 1967.

SIR,—We were interested to read the communication by Dr. I. D. Green (2 September, p. 593). However, we are not at all clear how the mean F_{IO_2} was obtained from the mass spectrometer trace. A true mean value is obtained only if the concentration trace is weighted in proportion to the instantaneous flow rate.[1] Even then it is necessary to distinguish between the mean concentration reaching the alveoli and the mean concentration reaching alveoli plus dead space.

These difficulties can be bypassed in normal subjects by using alveolar sampling, which provides a direct measure of the alveolar oxygen concentration produced by any device.[2] Arterial catheterization is avoided in this method. The dead space of each device can be determined quantitatively if the subject's ventilation is also measured.[3]

From the results of our own study[3] we do not consider a nasal catheter a reliable method of delivering oxygen unless it is inserted as far as the oropharynx, and our own preference for any hypoxic hypercarbic patient is the Ventimask. The Pneumask and the Polymask, especially the former, should be regarded as dangerous, in our opinion. If high oxygen concentrations are required the M.C. mask is nearly as effective and has a much lower dead space at all oxygen flows.

Dr. Green's comments on patient comfort are very pertinent; it is our experience that there is a marked inverse correlation between the effective dead space of a mask and the degree of patient comfort.—We are, etc.,

Calcium Infusion Test

SIR,—We would agree with Dr. J. V. Lever, Dr. C. R. Paterson, and Dr. D. B. Morgan (29 July, p. 281) that a positive calcium infusion test does not always indicate histological osteomalacia, but would dispute their conclusion that for this reason the test is of no value.

Among 12 patients with chronic obstructive jaundice studied at the Royal Free Hospital six had a retention of calcium greater than that found in a control group of patients.[1] After one to three months of parenteral vitamin-D therapy the calcium infusion test remained abnormal in all except one patient, but after twelve months of treatment all these patients had a normal calcium infusion test. Although only one of the six patients had osteomalacia on biopsy, all of them clearly had some biochemical abnormality which was corrected by long-term vitamin-D treatment. On the other hand, in the four patients with subnormal calcium absorption this was restored to normal by a short course of vitamin D.

A normal calcium infusion test probably excludes osteomalacia, and may thereby spare many patients an unnecessary bone biopsy. Furthermore, an abnormal result may be the only biochemical indication that osteomalacia is present.[2] The test clearly merits further evaluation.—We are, etc.,

Haematomas of the Abdominal Wall

SIR,—I was interested in the correspondence (8 July, pp. 108 and 109) subsequent to your leading article (17 June, p. 716) on the above subject.

Two cases of this condition have been referred to me and there had been two other cases in the same hospital six months previously.

The patient was 24 weeks pregnant in her fifth pregnancy and had had a severe cold and cough for three weeks previous to admission, but this had greatly improved in the past few days. An acute pain had awoken her in the early morning. She was in shock, and the diagnosis of intra-abdominal haemorrhage was made with some misgivings, as the findings were atypical, and there was no shoulder pain such as should have been present with the amount of shock seen. At operation, the true state of affairs was evident. There was a rupture of the left rectus abdominis muscle below the umbilicus. Bleeding was continuing from small vessels in the muscle and there was a small haematoma beneath the muscle. Haemostasis was achieved and the abdominal wall closed by continuous suture without drainage. A sinus formed and there was a serous discharge for three weeks. Delivery of a live baby at term was normal.

The second patient was admitted as an emergency at 32 weeks' gestation in her fourth pregnancy, which had been eventless except for a mild cold and cough in the previous two weeks. She had severe left-sided lower abdominal pain with shock, and was diagnosed as a possible rupture of the gravid uterus. Lateral radiographs of the abdominal wall showed a definite area of dehiscence of the anterior musculature in the region of maximal tenderness on shallow palpation. Laparotomy was withheld and under muscle relaxants and analgesia the symptoms subsided. Delivery at term was uncomplicated and the infant alive.

All four patients were pregnant and multiparae, and all had recently had a head cold and associated cough, though none attributed the onset of the pain to any episode of coughing. All were grossly overweight with poor abdominal muscle tone. The two patients who had lateral abdominal *x*-rays taken showed a recognizable defect of the soft tissues, and this is a valuable diagnostic point in the differential between intra-abdominal haemorrhage and lesions of the abdominal wall.

The diagnosis is not simple, and, as pointed out,[1-3] under 30% are diagnosed before operation. The mortality rate is high in both mother and foetus, and this is felt to be an indication of preceding debility, which is also held to be predisposing. Where the deep epigastric arteries are torn and continue bleeding then operative therapy is mandatory.[4]—I am, etc.,

Diet and Diverticulitis

SIR,—I have read with great interest the comments on this subject made by Dr. C. D. Campbell in his letter (22 July, p. 243) and the one before (2 July 1966, p. 50) jointly with Dr. T. L. Cleave. They have strongly related colonic diverticular disease to the consumption of refined carbohydrate in any community irrespective of racial differences. Their view is rightly opposed by Dr. E. H. Goulston expressed in his letter (6 May, p. 378), at least as far as Ethiopians are concerned. Our experience in Kuwait conforms to the latter one.

Kuwait is inhabited mostly by Arabs and shared by large minorities of other nationalities, particularly Persians, Indians, and Pakistanis. We import nearly all our food items from all over the world, including refined wheat grain flour, rice, fruits, and vegetables. There is no doubt that this diet consists mainly of refined carbohydrates. Nevertheless, not a single case of diverticulitis has ever been seen in our department. Over the last three years 284 barium enemata were performed for various colonic disorders without showing any evidence of diverticulitis. Only in one case two small diverticula were detected in the sigmoid colon. On the other hand, diseases such as ischaemic heart disease, diabetes mellitus, in which diet is incriminated, and ulcerative colitis are found more or less in the same incidence as in Western countries. Therefore it is hard to accept that diverticulitis is the result of refined carbohydrate consumption.—I am, etc.,

Dose of Metaraminol

SIR,—In the June 1967 addition to "Proplist," on page 7, the dosage for Aramine (metaraminol tartrate) given intravenously is shown as 15 mg.–100 mg. This, of course, is the dosage for intravenous infusion to be placed in 500 ml. isotonic saline or 5% dextrose, and the dosage for direct intravenous injection is 0.5 mg. to 5 mg.—I am, etc.,

Progestin Therapy of Breast Cancer

SIR,—The letter of Dr. B. Jolles on this subject (9 September, p. 682) is to be welcomed because of his important early work on the progestin therapy of cancer.[1] He stresses the possible advantage of combined oestrogen and progestin therapy in cancer of the breast as suggested by Landau *et al.*[2] It was on the basis of that very report that I carried out two clinical trials, which have both been reported.[3,4] In the first I *added* progestin therapy after stilboestrol 15 mg. daily had failed to induce regression of breast cancer. Response was noted in 3 out of 10 patients. In the second series I gave a progestin-oestrogen combination in the proportion used in the contraceptive pill. Response was noted in 9 out of 65 patients, and 5 out of the 9 had previously received and failed to respond to oestrogen or androgen therapy.

I therefore welcome a preliminary report by Dr. Jolles of a 32% response in 25 patients with breast cancer treated by a combination of 19-nor-17αhydroxyprogesterone with oestradiol. I look forward to examining the criteria of response used by him to account for this response rate. It will be interesting to know how many of the patients were treated by the combination after having failed to respond to the oestrogen alone. Only in this way, or by a controlled trial, can the value of the added progestin be assessed.

Dr. Jolles's final statement suggests that he read my paper[5] very carelessly. He states, "Effects on vaginal smears are not likely to be more reliable in this regard [in establishing potency ratios of progestins] in postmenopausal women, and caution should be exercised in drawing conclusions for the selection of patients suitable for this type of hormone therapy." I did not anywhere suggest that the *effect* of progestins on the vaginal smear could be used for selection of patients suitable for such therapy. I made it clear that the initial vaginal smear *before* therapy seemed to suggest a method of selecting patients more likely to respond to progestin therapy. My results suggested that the absence of oestrogen secretion in postmenopausal patients, as shown by an atrophic smear, militated against the likelihood of successful progestin therapy. This observation tends to confirm the suggestion made in the second sentence of this letter.—I am, etc.,

Sodium Chlorate Poisoning

SIR,—Renal failure due to sodium chlorate poisoning is, we believe, less rare than suggested by Dr. R. K. Knight and colleagues in their report of a case (2 September, p. 601). We reported three instances, with recovery, in 1963 among a large group of patients with severe acute renal failure treated with haemodialysis.[1]

One patient who attempted suicide on two separate occasions at a nine-month interval is of particular interest, since he demonstrates how complete recovery may ultimately be despite two severe episodes of acute renal failure with as powerful a nephrotoxin as sodium chlorate. The first admission was in May 1961, after swallowing five tablespoonfuls of sodium chlorate. He had the typical clinical and laboratory features of gross intravascular haemolysis and acute renal failure. Vitamin C was administered and haemodialysis was performed on admission in an attempt to remove sodium chlorate. The oliguric phase of the renal failure lasted for 14 days, and he required two further haemodialyses to control uraemia; the daily rise in blood urea averaged 80 mg./100 ml. At the time of discharge, to receive psychiatric treatment, creatinine clearance was 25 ml./min., and by August 1961 it had risen to 54 ml./min. In September 1961 he again attempted suicide, on this occasion swallowing a half-tumblerful of sodium chlorate. He was managed in a similar way with haemodialysis on admission, followed by a second haemodialysis four days later to control uraemia. The oliguric phase lasted seven days, and the daily rise in blood urea averaged 50 mg./100 ml. Renal biopsy in October 1961 showed considerable tubular atrophy, and it was felt likely that ultimate recovery of renal function would be incomplete.

He received inpatient psychiatric care for several weeks with marked improvement in his mental state, and returned to work. He was seen again in January 1966 as part of our recent study into the late prognosis of acute tubular necrosis,[2] and we were gratified to find him well, with a creatinine clearance of 90 ml./min. The only slight abnormality apparent was that the maximum urinary specific gravity after dehydration was 1.017.

The second patient[1] was a 65-year-old male gardener, who had taken a similar amount of sodium chlorate in a suicidal attempt. The oliguric phase of the renal failure was rather more prolonged, being 16 days, the average daily rise in blood urea was 80 mg./100 ml., and he required four haemodialyses in all.

He made a good immediate recovery from the acute renal failure and was discharged, but we were unable to determine the long-term prognosis because of his death from an unrelated cause.—We are, etc.,

Disturbed Geriatric Patients

SIR,—In our letter (2 September, p. 614), which you were good enough to publish, you have omitted, doubtless for reasons of space, details about the positions held by each of us which were included in our version. We write to correct this, partly because only one of us (and not all three as implied in the published letter) is on the staff of the Department of Psychological Medicine. A more important reason is that our views were derived from experience of co-operation by four separate organizations concerned with the care of the elderly, that are often separated from one another by administrative barriers: the Health and Social Services Department of the City and County of Newcastle upon Tyne; departments of geriatrics in a general hospital and a local mental hospital under the aegis of the regional hospital board; and the University Department of Psychiatry. These facts appeared to us to deserve a note of correction.—We are, etc.,

Early Discharge of Maternity Patients

SIR,—The leading article "Early Discharge of Maternity Patients" (26 August, p. 508) makes the unqualified statement that "The doubts about the dangers to mother and baby from early discharge are largely dispelled by the Bradford reports" as though this were a new discovery. May I therefore bring to your attention a paper which appeared in the *Lancet* three years ago?[1]

In it you will observe that during a 12-month period in 1962/63, in the County Borough of Wolverhampton, a carefully designed *prospective* survey of *random* early discharge from hospital of 1,044 mothers and 1,044 babies, each of whom was followed up objectively for two months after confinement, made these important findings: that mortality was non-existent in mothers and small in babies; that morbidity was low for both; that neither could be attributed to early discharge; and that race, not duration of stay, was the most decisive and highly significant factor in establishment and maintenance of breast feeding.

It should be added that the final survey confirmed the results of a pilot survey—to test methodology and recording—of 969 simultaneous mother and baby discharges over the preceding twelve months and that it assisted substantially in presentation earlier this year of a case for the revision of the bed ratio on which planning of hospital maternity resources is based.[2]—I am, etc.,

Future of General Practice

SIR,—Your gratuitous stricture of "successive Ministers of Health" (12 August, p. 383) might have been allowed to pass were it not coupled with that of "their administrations" as being responsible for the recent nadir of general practice, and the lack of "responsibilities towards their medical employees." The "administrations" include doctors, who, by their position, will hardly be able to reply and set the record straight. Not enough is known of their efforts, under what must have been well-nigh impossible conditions, to alleviate the results of B.M.A. policy; their known contributions deserve better.

The previous insistence on the myth of the general practitioner being an independent contractor has been the greatest obstacle to development, which is now hailed as a must. (A re-reading of the Cohen Report[1] will show this.) The recognition that most general practitioners are employees *de facto* if not *de jure* enables them now to claim rights. Their previous "independence" made them shoulder responsibilities that have worn them down. That it is still possible for general practice to develop is a credit (I would hazard) no less to the Ministry's medical advisers than to the political acumen of various Ministers in avoiding the cul-de-sac into which the Association's policy on general practice would have led. The continuous discussion about general practice outside the N.H.S. shows how much further thought is necessary among some influential leaders.

Apart from the political misappraisals, I would suggest that the future role assessment is also incorrect. Is the future development of general practice to be confined to "practice in groups and closer association with hospitals"?

Vickers[2] contrasts inpatient and community medicine; "about 1% of the population at any one time are not to be found in the world of the well." He continues, "The purpose of community medicine is far wider; it is responsible for managing, in the world of the well, the human estate of sickness and mortality. I include in this the management of the non-pathological crises of life, birth, growth, senescence—death also, unless we regard death as always pathological—and the management of all illnesses, whether curable or not." Words which many family doctors will readily warm to. The future of general practice with an ancillary role to the 1% in hospitals seems rather narrow compared with the needs of many of the 99% outside.

It might be that the Seebohm Committee in its deliberations on a family service will suggest a broader role for the general practitioners, but the profession itself must explore and transcend the old definitions in the face of new needs and possibilities. No less than the hospitals, the medical officers of health and community medicine must be seen as points of growth for general practice.—I am, etc.,

Birmingham. BERNARD BARNETT.

Computer Control

SIR,—May I draw the attention of medical officers who are employed or paid by more than one authority to what can only be called bureaucratic dominance by computer. All employees have to contribute towards the National Graduated Pension Scheme. The maximum amount that can be deducted is 9s. 3d. per month. However, if a person is employed or paid by more than one authority, each authority deducts an amount—scaled down to the gross salary received by each—8s. 7d. being the next rate.

I challenged the Ministry of Social Security about this, and after a lengthy wait I was informed that my county authority was willing to accept the responsibility of paying my full salary, but agreement would have to be reached with my other authorities regarding reimbursement.

The Ministry in its letter to me stated: "In any scheme involving the majority of the working population the rules must be as simple as possible . . . when a person has two or more employments it is easier administratively for each employment to be treated separately and for graduated contributions to be deducted by each employer; excess payment being refunded on the completion of the person's insurance records at the end of the year." The Ministry do not reveal that no refund is made to the employers. The employers' contribution is double that of the employee. In the case of local authorities this means an unnecessary burden being placed on the ratepayers.

I would have thought that the authorities concerned would have been quite capable of making adjustments locally—either by paying the stamp in rotation or by making a cash adjustment. This is not permitted by the Ministry of Social Security—it would interfere with the computer programme.

The amount is small in a monetary sense, but it will not grow less, and the principle of employee and ratepayers being sacrificed to bureaucratic administrative expediency is wrong. I am sure that there must be a considerable number of medical officers in this situation. Is this a case for the Government Ombudsman?—I am, etc.,

ALEXANDER DONALDSON.

Bedlington,
Northumberland.

Night Visits

SIR,—Recently I have had to make four visits during the night to patients who were extremely ill. The first was a lady who I suspected had a pulmonary embolism and whose heart had stopped beating. Fortunately, by means of external cardiac massage and mouth-to-mouth respiration, she survived and is now well. Two of the other cases were old people with acute left ventricular failure, and the last was a patient who unfortunately died of bronchial asthma.

Probably to the delight of the Ministry of Health I am afraid I had neither the time, opportunity, nor inclination to ask them to sign the night-visit form. Could not we be trusted just to sign a list at the end of the quarter giving the names of patients and the nights on which they were visited?—I am, etc.,

King's Lynn,
Norfolk. J. D. WIGDAHL.

Points from Letters

Changed Character of Osteomyelitis

Mr. H. R. W. LUNT (Derby) writes: Two points made by Mr. N. H. Harris (9 September, p. 680) seem to require elucidation: (1) In the matter of operation I have been able to show, among 59 strictly comparable cases of long-bone osteomyelitis, that operation is only of significant value when the patient is received some four days after onset of the symptoms, speaking in general. After this stage pus is usually present, and it is important to let it out as soon as possible. (2) With regard to tetracycline, we find this is indeed a valuable drug.

Role of the Married Nurse

Dr. P. H. KIDNER (London E.9) writes: Nurses, even when wives and mothers, can be of considerable use to the hospital and society. The answer to the married nurse and work is not the crèche. The real answer is the part-time appointment with an adequate salary and proper and permanent status. Like it or not, some such answer will have to be found. The floating population of the "co-operative nurse" is creeping even into the teaching hospital. Many of my colleagues are married to nurses both willing and able to return to work if some attempt is made to meet them half-way. The nursing shortage is becoming acute. The day of the woman completely and utterly dedicated to full-time nursing has gone—and why not? Wives can be nurses and mothers too.

Obituary Notices

H. A. MAGNUS, M.D., F.R.C.P., F.C.PATH.

Professor H. A. Magnus, director of the pathology department at King's College Hospital, London, and professor of morbid anatomy, died suddenly on 12 September. He was 57.

Henry Adolphe Magnus was born on 11 November 1909, and was educated at Mill Hill School and St. Bartholomew's Hospital, London, qualifying with the Conjoint diploma in 1932, and graduating M.B., B.S. the following year. He held early house appointments at St. Bartholomew's Hospital, and in 1934 became resident medical officer at Papworth Village Settlement. In the same year he was appointed research assistant to the bacteriology department at St. Bartholomew's Hospital, and in 1935 became senior demonstrator in anatomy. In 1937 he was appointed lecturer in morbid anatomy and histology. At the outbreak of the second world war he joined the R.A.M.C. as specialist pathologist, serving overseas with the 9th Army and Eastern Command. After demobilization with the rank of lieutenant-colonel he returned to his post at St. Bartholomew's Hospital. In July 1946 he was appointed morbid anatomist at King's College Hospital, director of the pathology department in 1947, and professor of morbid anatomy at King's College Hospital Medical School, University of London, in 1948. In 1949 he became a member of the Royal College of Physicians, and in 1956 was elected F.R.C.P.

Magnus was, in addition, a member of the Board of Governors of King's College Hospital; he was an examiner for the Primary F.R.C.S. and F.F.A. R.C.S., as well as for the University of London and the Conjoint Board. He was a member of the Pathological Society of Great Britain and Ireland, and of the Association of Clinical Pathologists, and honorary secretary and vice-president of the section of pathology of the Royal Society of Medicine. He was honorary secretary of the section of pathology and bacteriology at the Annual Meeting of the British Medical Association in 1949. From 1960 to 1964 he was president of the Institute of Medical Laboratory Technicians, and in 1964 he became a Fellow of the College of Pathologists. Since 1956 he had been a valued member of the editorial board of the *Journal of Clinical Pathology*.

In 1935 he married Miss Kathleen Aiken, who survives him together with their two sons.

A colleague writes: When Magnus came to King's in 1946 the pathology department was just beginning to expand and to recover from the considerable disruption caused by the second world war and the evacuation of the main laboratory to Epsom. His flair for organization soon became apparent, and one of his major memorials at King's is the division of pathology, composed of four academic departments, each headed by a professor. In the early postwar days whole-time academic staff were a new and strange species at King's, and it was very largely due to the immensely human and vital personality of "the Prof." that they became accepted so rapidly. "Dick" Magnus was no dry academic; he had the happy knack of being interested in the patient as well as the disease, in the personality of his medical and technical staff as well as in their academic and professional abilities, and in the welfare of the medical students as much as in their transformation to doctors. Because of his intense interest in people, colleagues and students often sought his advice, and many will remember with gratitude his help in time of difficulty. As a teacher he was most stimulating, seasoning necessary facts with a wealth of apposite stories, and recalling with astonishing and vivid detail illustrative cases from his wide experience. He was popular with the students, and was often depicted with affection in the Christmas pantomime. Outside the hospital he had many interests, particularly gardening and deep-sea fishing. His enthusiasm for these hobbies was infectious; he would often give an entertaining and informative discourse on them, and on life in South Cornwall, where he spent his holidays. His sudden and early death comes as a sad loss to his friends and to King's. To his wife and two sons we offer our sincere sympathy.

EWEN CAMERON, M.D., F.R.C.P.(C.) D.P.M.

Professor Ewen Cameron, who had occupied the chair of psychiatry at McGill University and was the first president of the World Psychiatric Association, died suddenly at Lake Placid, New York, on 8 September. He was 65.

Donald Ewen Cameron was born at Bridge of Allan, Perthshire, on 24 December 1901, and received his medical education at the University of Glasgow, graduating M.B., Ch.B. with distinction in 1924. He took the D.P.M. in 1926, and proceeded M.D. with distinction in 1936. After early house appointments he was for a time assistant physician at Glasgow Royal Mental Hospital with Dr. D. K. (later Sir David) Henderson before going to train and work with Adolf Meyer at Phipps Clinic at Johns Hopkins Hospital from 1926 to 1928, and later with Bleuler at Zurich. At this point he was lost to British psychiatry, and returned to work in the U.S.A., soon becoming psychiatrist-in-chief at Albany Hospital, New York. In 1942 he became an American citizen, but very soon was appointed to the psychiatric department of McGill University, Montreal, Canada, of which he became a distinguished head. Here he became professor of psychiatry and director of the Allan Memorial Institute of Psychiatry. A little later he was chosen to be one of the experts gathered to decide the fate of Hess at Nuremberg, which resulted in his present detention in Spandau, rather than his being executed, because of mental illness. He became president of the American Psychiatric Association as early as 1952, among his many other honours. In 1961 he organized the 3rd World Congress of Psychiatry in Montreal, where the World Psychiatric Association was formed, and he became its first president.

Cameron had great organizing abilities, but he remained a clinician till the end. He always insisted on treating a number of his patients himself personally, rather than sitting too much in his professorial chair, which also carried so many administrative and teaching responsibilities. By this means he always remained aware of the individual patient's problems, and was able to discuss treatment matters from personal experience.

He did not always tolerate fools gladly, but supported with all his energies those he felt were doing all they could to improve the treatment of the mentally ill. He refused to follow the craze for psychoanalysis which swept American medical schools after the second world war. But, like Adolf Meyer and Henderson, he welcomed all types of approach being used at his clinics, provided patients were being helped rather than loose theories being propounded. He became interested in transcultural psychiatry, and encouraged the development of a special department for this. He had enormous numbers of psychiatrists in training, coming from all over the world, towards the end of his climb to world fame.

Cameron died as he would have wished—in full and very active harness, still planning his future research programme, and having specially moved to Albany to work which he could carry on beyond the normal age of retirement. It was also only a year ago that he had given up being the dynamic stimulator of the new World Psychiatric Association, of which he became the first president for a period of five years. He was one of the great clinical school of Scottish psychiatrists which have done so much in the last 50 years to spread good clinical psychiatry all over the world, their country's loss being others' gain. Getting up at 6 a.m. to do his writing, he worked very long hours to the end. He may well have died earlier than he needed to because of all his work for others. Last year, at the 4th World Congress of Psychiatry, he was still full of energy and planning for the future. It is difficult to think of his not being with us any more.

Ewen Cameron, by his work and example, helped not only many psychiatrists to become much better doctors but directly and indirectly helped hundreds and hundreds of patients, both personally and through those he had inspired and taught. He was always helped by a wonderful wife, Jean Rankine, a famous tennis player and a very human person. Her consolation will always be that he died continuing to help others to a better and fuller life, perhaps at the expense of his own health and life. But he would not have wished otherwise. I have lost a much admired and inspiring friend, and so have many other people.—W. S.

R. V. HUDSON, F.R.C.S.

Mr. R. V. Hudson, honorary consulting surgeon to the Middlesex Hospital, London, died in Monmouth on 10 September. He was 72.

Rupert Vaughan Hudson, son of Dr. J. W. Hudson, was born in January 1895, and was educated at Epsom College and the Middlesex Hospital Medical School. His studies were interrupted by the first world war, during which he served with the Hertfordshire Yeomanry and Cavalry Reserve, attaining commissioned rank. He returned to his medical studies on demobilization, and qualified with the Conjoint diploma in 1922. After holding early house appointments at the Middlesex Hospital he was appointed to the surgical staff, and took the F.R.C.S. in 1927. He became lecturer in operative surgery to the medical school and honorary consulting surgeon to the Middlesex Hospital; he was consulting surgeon to the Connaught Hospital at Walthamstow, to St. Saviour's Hospital, and to the Royal Infant Orphanage at Wanstead. Also he was examiner in surgery to the Universities of London and Cambridge, and a member of the committee for the therapeutic trials of penicillin and streptomycin. He married in 1929 Esme, daughter of Gladstone Wilson, and they had a son and two daughters.

D. H. P. writes: Vaughan Hudson left his mark at Middlesex, both as a student and as a member of the consultant surgical staff. Well built and handsome, he was a natural athlete. As a student he was a leading member of all the clubs, excelling particularly at cricket, which he had played for his county as a schoolboy. In spite of his prowess, however, he always regarded games as a secondary pursuit, a striking illustration of this being his turning down the chance to be a regular member of his county cricket team because this would interfere with what he regarded as the more important things of life. He was house surgeon, and subsequently surgical registrar, to Gordon Taylor, who made no secret of the fact that he regarded him as the most brilliant of his young men. On his appointment to the surgical staff of the Middlesex, Hudson was at first junior surgeon on Gordon Taylor's firm. He interested himself particularly in thyroid surgery. With the late Bernard Johnson as his anaesthetist, he developed more delicate and refined techniques for thyroidectomy than were then current in this country, inventing in the process instruments which are still a joy to handle. Just about this time Professor Charles Dodds established in the Courtauld Institute of Biochemistry, under the late Douglas Robertson, a basal metabolic unit to develop the therapeutic possibilities of this investigation in thyrotoxicosis. Until the establishment of the unit this country lagged behind the United States in the treatment of thyrotoxicosis, and many leading thyroid surgeons regarded the basal metabolic rate as unreliable, and as adding nothing to clinical assessment. Robertson and Hudson between them confirmed the American work on the necessity for an objective test to supplement clinical assessment if surgery for thyrotoxicosis was to be safe, and gradually converted the sceptics.

But Hudson's major contribution to medicine did not come till after the second world war and towards the end of his active career. This was the publication, with Dr. Deborah Doniach and Dr. I. M. Roitt, in October 1956, which demonstrated the importance of autoimmune factors in Hashimoto's thyroiditis —a paper which opened the gates for a flood of new investigations which are still profoundly influencing our understanding of disease processes. This work rapidly developed into a highly specialized complex, of which the surgeon perforce became merely an intensely interested onlooker. Hudson, however, deserves his full share of credit for first seeing that an obscure and uncommon condition of apparently minor importance was worthy of intensive investigation. This achievement was not fortuitous but the logical culmination of an attitude of a professional lifetime.

Hudson often found it difficult to express his ideas clearly, but his colleagues learnt that it was unwise on this account to dismiss them. I remember vividly a number of important occasions when Hudson resolved a complex situation of conflicting interests and opinions by reducing it to the two simple questions: what is the course most likely to lead to the advance of medicine? and, what is the course most likely to be for the good of the Middlesex and the medical school? Rupert Hudson managed to combine reserve and dignity with the capacity to be an easy and delightful companion, and he always respected the reserve and dignity of others. These characteristics made him popular with his colleagues, and, combined with his handsome appearance and obvious professional skill, won him the affection of his patients.

ISABEL M. S. REID, M.B., J.P.

Dr. I. M. S. Reid, a general practitioner in East Yorkshire, was killed in a railway accident on 31 July. She was 48.

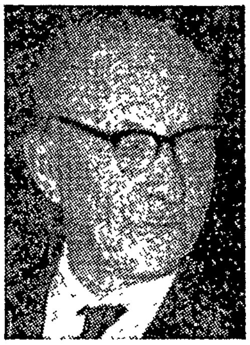
Isabel Mary Smart Reid (née Chalmers) was born in Keith in 1919, and received her medical education at Aberdeen University, where she graduated M.B., Ch.B. in 1942. She started with some general practice at Keith, and then took a post as house-surgeon in Aberdeen Royal Infirmary. After this she was house-officer in obstetrics in the Southern General Hospital, Glasgow. In 1944 she returned to general practice at Inverbervie, and remained there until she married David Reid in 1946. They went to live first at Winchester and then Maidstone, and during this time she maintained her interest in general practice. Twelve years ago the family moved to Hull, where she took a course in family planning and worked in both family planning clinics and public health centres, as well as continuing with general practice. Her major work was in the family planning clinics at Hull and in the East Riding, where she made a valuable contribution. She was appointed to the magistrates' bench a few years ago, where her work was much appreciated. Her humane personality, as well as her professional experience, enabled her to be a most excellent justice.

Isabel Reid was of a happy and kindly disposition which endeared her to all her fellow students in Aberdeen University. In practice and in her hospital work she was admired for her conscientiousness and great efficiency, and was full of unselfish consideration for others, which brought her love and respect from both patients and colleagues. She was devoted to her husband and her two sons, and managed to look after her family as well as maintain her keen interest in medicine. Those of us who had the privilege of enjoying her friendship and the hospitality of her gracious home will especially mourn her sudden passing. She will be sadly missed by all her friends, and our deepest sympathy goes out to her husband and sons in their irreparable loss.—I. M. S. and I. D. I.

F. R. BROWN, O.B.E., M.B., CH.B. F.R.C.S.ED.

Mr. F. R. Brown, surgeon emeritus, Dundee Royal Infirmary, died at his home in Dundee on 7 September after a long illness. He was 77.

Francis Robert Brown, son of a Roxburgh farmer, was born near Melrose on 20 September 1889, and was educated at Edinburgh University, graduating M.B., Ch.B. in 1913. After an early appointment as house-surgeon at Glasgow Royal Infirmary he returned to Edinburgh as house-surgeon at the Hospital for Sick Children. During the first world war he served with the R.A.M.C. in Salonika and the Caucasus. He was thrice mentioned in dispatches, and was awarded the O.B.E., and, in addition, the Order of St. Stanislaus. After demobilization with the rank of major he returned to Edinburgh, and in 1920 was elected a Fellow of the Royal College of Surgeons of Edinburgh, going at the end of the year to Dundee as assistant to the late Professor L. Turton Price. In 1931 he was appointed assistant in the department of surgery at University College, Dundee (now the University of Dundee), and an assistant surgeon at Dundee Royal Infirmary, becoming senior surgeon on the retirement of Professor R. C. Alexander in 1951.



Mr. Brown was an examiner at the Universities of Edinburgh, Glasgow, and Newcastle, and in 1938–9 was president of the Dundee Branch of the British Medical Association. He was a consultant surgeon to the Eastern Regional Hospital Board of Scotland until 1956, in which year he became a senior Fellow of the Association of Surgeons of Great Britain and Ireland. He retired in 1959, but continued in private practice. His wife died in 1952, and he is survived by a daughter and two sons.

D. M. D. writes: For almost 40 years Frank Brown was a notable figure in the medical school in Dundee. A pioneer in many fields of surgery, most notably in the surgery of the heart and great vessels, he remained a general surgeon. He had the gift of a neat, rapid operating technique, so that he never appeared to hurry, even in complex cases, and his results were excellent. After his retirement he had the unusual honour of being appointed reader in surgery at the University of St. Andrews. This by tradition is reserved for members of staff of special distinction.

Frank Brown's original and stimulating mind attracted outstanding young men to his side, and four of his house-surgeons occupy chairs in medical schools at home and abroad. He was an entertaining companion on any occasion, but particularly on his beloved South Esk, where his knowledge of the ways of trout and salmon made a day's fishing a memorable lesson in natural history. Although an outstanding athlete himself, he was a vigorous opponent of professional boxing, pointing out that this was the only form of athletics in which the infliction of head injuries was the primary aim.

His kindness to young men in surgery has left a host of devoted friends all over the world. They will be sad to hear of his passing, but grateful for the memory of a fine surgeon and a good companion.

S. F. S. writes: There are few branches of surgery in which Frank Brown was not actively interested. Although latterly he confined himself mainly to the field of gastroenterology, when first I had the good fortune to work with him he was also busily engaged in cardiac and orthopaedic surgery, and regularly performed leucotomies. He was a supreme technician, unhurried and unruffled, bringing to each operation the scrupulous skill and delicate touch which he had learned from his old teacher, Sir Harold Stiles. The expanding horizons of surgery attracted him; new methods were constantly introduced, and, once mastered, a search for new ventures began. His abiding interest was referred abdominal pain (although he disliked the term), and he contributed a number of papers on this subject. But he also held decided views on other matters—on the dangers of boxing and the use of a round ball in rugby football—and these he forcibly expressed from time to time in the local press. A former Border rugby player, he retained his interest in sport throughout his life. At one time a low handicap golfer, he latterly gave up the game, which he maintained was too easy—"like shooting a sitting bird"—to spend his leisure hours on river and moor. His hospitality to his junior colleagues on the South Esk was generous. He regularly attended meetings of the Moynihan Chirurgical Club, where his infectious good humour and gay spirit made him an ideal travelling companion. He was a man of great charm, modesty, and ease of manner who greatly valued the friendship of his numerous house-surgeons and registrars, in whose affairs he took the keenest interest and pride.

A. M. HENDRY, M.B., CH.B., F.R.C.S.ED.

Mr. A. M. Hendry, a leading Midland orthopaedic surgeon, died in the Queen Elizabeth Hospital, Birmingham, on 10 September. He was 70.

Anthony Morrice Hendry was born at Fraserburgh, Aberdeen, on 11 November 1896, and received his education at Fraserburgh Academy and the University of Aberdeen Medical School. His studies were interrupted by the first world war, during which he served in the Royal Navy aboard a minesweeper. After demobilization he resumed his studies, graduating M.B., Ch.B. with first-class honours in 1924. He became house-surgeon at the Royal Hospital for Sick Children in Aberdeen before moving south to Birmingham, where he was appointed resident surgical officer at the Ministry of Pensions Hospital, Highbury. This step was to determine his whole surgical career, since he worked directly under the late Mr. Naughton Dunn, and through him came under the influence of the late Sir Robert Jones. After some years at Highbury he went back to Aberdeen as assistant in the anatomy department, and took the F.R.C.S.Ed. in 1930. He then returned to Birmingham, and was appointed assistant surgeon to the Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry; assistant orthopaedic surgeon to the Corbett Hospital, Stourbridge; and clinical assistant to the Royal Orthopaedic Hospital, Birmingham. He later became senior visiting surgeon to the Robert Jones and Agnes Hunt Hospital, surgeon to the Royal Orthopaedic Hospital, fracture and orthopaedic surgeon to the Corbett Hospital, Stourbridge, and honorary consulting orthopaedic surgeon to the Infirmary, Burton-on-Trent. He also served as orthopaedic specialist to the Ministry of Pensions, Midland Region, and was a member of the medical appeal tribunal of the Ministry of Pensions and National Insurance. During the second world war, in addition to his normal commitments, he became a member of the Emergency Medical Service, orthopaedic surgeon to the War Emergency Hospital at Barnsley Hall, Bromsgrove, and at the Derwen Rehabilitation Centre at Gobowen.

He was a fellow of the British Orthopaedic Association, and served on its executive committee, a member of the Société Internationale de Chirurgie Orthopédique et Traumatologique, and a member of the Naughton Dunn Club. For many years he was secretary to the Midlands Aberdeen Medical Graduates Association, and later became its president. He was vice-president of the section of orthopaedics at the Annual Meeting of the British Medical Association in 1953.

One of Hendry's great contributions to orthopaedic surgery was in the training of young surgeons. He was instrumental in persuading many young Scottish surgeons to come to the Royal Orthopaedic Hospital and to the Robert Jones and Agnes Hunt Hospital to work as residents under his guidance. His surgical judgement was of the highest order, and his operative technique confident and easy. He was never in a hurry, and always had time for every patient and to answer every question. He was a man of unbending principles, yet just and generous, especially towards his juniors. He had a ready wit, and was enthusiastically welcomed at all social functions.

His contributions to the literature were few but authoritative, and his article on the treatment of residual paralysis after brachial plexus injuries is regarded as a classic. He will be remembered for his courtesy, kindness, and consideration by all his patients and for his unfailing generosity by his countless friends.

He married Miss E. M. Lilley in November 1934, and is survived by his widow, by a daughter, and by his sons, to whom we extend our sympathy.—F. G. A.

J. G. STEVENS, M.R.C.S., L.R.C.P.

Dr. J. G. Stevens, formerly in general practice in Tooting, London, died suddenly on 8 August while on holiday in Ireland. He was 76.

John Greet Stevens was born in Portsmouth, on 20 March 1891, of a naval family, and was educated at Portsmouth Grammar School. He received his medical education at Guy's Hospital, qualifying with the Conjoint diploma in 1917. After an appointment as house-surgeon at Guy's Hospital, he served as surgeon lieutenant-commander in the Royal Navy until 1920. In 1919 he went to Archangel in the *London Belle*. After demobilization he became resident medical officer at the Weir Hospital, Balham, later joining the late Dr. M. M. Woods in general practice, and continued working in this district until 1958. For some years he was an anaesthetist at the Weir Hospital and the Fountain Hospital, London.

He is survived by his wife—their only son having been killed in 1943 while serving in the Royal Naval Reserve, Fleet Air Arm.

B. B. writes: I first met Dr. Stevens 40 years ago, when he was anaesthetist at the Weir Hospital, Balham. He was an able and conscientious practitioner with a remarkable clinical instinct. Kind, charming, and very busy, but never in a hurry, he always found time to chat over his cases. Even after his apparent retirement in 1958 he remained a keen clinician, and could be seen at all the local medical meetings. Held in high esteem by his colleagues, he spent his years of retirement doing locums, and was ever ready to give a helping hand. He enjoyed games, and excelled at tennis, which he played regularly, even after he had reached threescore years and ten. John Stevens was truly a family doctor of the old school, and his passing will be mourned by patients and fellow practitioners alike.

TERENCE EAST, M.A., D.M., F.R.C.P.

F. B. writes: The necessarily mainly factual account of Terence East's brilliant career leaves some scope, I feel, for an appreciation of other aspects of this many-sided and erudite cardiologist (obituary, 9 September, p. 68). A period of only three years between his graduation in 1921 and his election to the honorary staff in 1924 indicated not only the outstanding quality of Terence East but also a large measure of luck. But no one deserved this measure of luck more than Terence East, or justified to a greater degree the faith and good judgement of his senior colleagues who appointed him. It was my good fortune to be his first house-physician. I received from him much valuable tuition and encouragement, and many kindnesses. This was always especially gratifying from one who very definitely did not suffer fools gladly. We were especially happy to find him so serene in his retirement, with his many interests, not least in the cultivation of a garden exposed to the full force of Atlantic gales. We mourn the loss of a truly great scholar-physician.

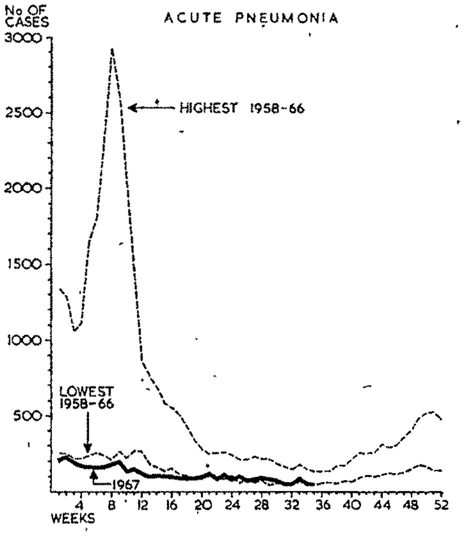
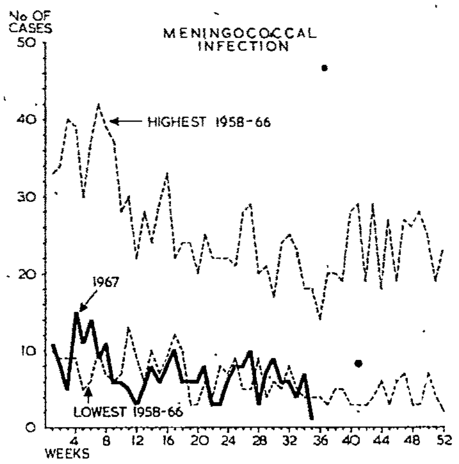
Graphs of Infectious Diseases

The graphs below show the uncorrected numbers of cases of acute pneumonia and meningococcal infection in England and Wales. Figures for 1967 are compared with the highest and lowest figures for each week in the previous years shown.





INFECTIOUS DISEASES AND VITAL STATISTICS

Summary for British Isles for week ending **2 September** (No. 35) and corresponding week 1966.

Figures of *cases* are for the countries shown and for Greater London. Figures of *deaths* and *births* are for the whole of England and Wales (London included), Greater London, the 17 principal towns in Scotland, the 10 principal towns in Northern Ireland, and the 14 principal towns in Eire.

A blank space denotes disease not notifiable or no return available.

The table is based on information supplied by the Registrars General of England and Wales, Scotland, N. Ireland, and Eire, the Ministry of Health and Local Government of N. Ireland, and the Department of Health of Eire.

MEDICAL NEWS

Professor of Physiology at Oxford

Professor David Whitteridge, F.R.S., has been appointed to the Waynflete Chair of Physiology in the University of Oxford in succession to Sir Lindor Brown, F.R.S., who has retired from the chair to become Principal of Hertford College. Professor Whitteridge was educated at Whitgift School, at Magdalen College, Oxford, where he took first-class honours in animal physiology in 1934, and at King's College Hospital, taking the B.M. in 1937. Returning to Oxford in 1938, he held a Beit Memorial Fellowship in 1940, the Schorstein Research Fellowship in 1944, and became a University Demonstrator in 1944. Having been a lecturer at Exeter and Balliol Colleges, he became a Fellow by special election at Magdalen College in 1945. In 1950 he succeeded Professor Ivan de Burgh Daly, F.R.S., as professor of physiology at Edinburgh. In 1953 he was elected to the Royal Society, in 1962 he received the Feldberg Prize, and in 1966 he was elected F.R.C.P. Among his other activities have been service as secretary of the Physiological Society between 1947 and 1951 and on its committee 1945–7 and 1951–5, and the presidency of the physiological section of the British Association in 1956. He has also been the editorial chairman of the *Quarterly Journal of Experimental Physiology.* His scientific work has been concerned chiefly with the physiology of vagal sensory fibres, the autonomic responses in patients with spinal injury (with Sir Ludwig Guttmann), the afferent responses from ocular muscles (with Dr. Sybil Cooper and Professor P. M. Daniel), and more recently the organization of the visual pathways and visual cortex.

[Walter Stoneman

Chair of Community Health

Professor Edward Maurice Backett has been appointed to the Foundation Chair of Community Health in the Medical School of the University of Nottingham. Professor Backett, who was educated at University College, London, and Westminster Hospital, qualified in 1944. Subsequently he served in the Royal Air Force, where he studied personnel selection and morale. In 1948 he became a Nuffield Fellow in Social Medicine, and in 1950 he took the M.R.C.P. Subsequently he taught social medicine and epidemiology at Queen's University, Belfast, at Guy's Hospital, and the London School of Hygiene and Tropical Medicine. In 1965 he was elected F.R.C.P.

Professor Backett became the first professor of social medicine in the University of Aberdeen in 1958. This department, which has two associated units (a medical records research unit and a general practice teaching and research unit), has been concerned with the evaluation of health services, the epidemiology of chronic disease, and geriatric care. Professor Backett's research interests have been mainly in the epidemiology of gastrointestinal cancers and duodenal ulcer, the organization of general practice, the problem of accidental death and injury, and in teaching methods. He has been particularly concerned with the development of his subject in Latin America and India, and with collaboration between different disciplines in teaching.

U.S. Professor at Glasgow

Professor Lewis L. Engel, the American Cancer Society professor of biological chemistry at Harvard Medical School, has been appointed to the Macfarlane Chair of Experimental Medicine at Glasgow University. He will work for a year from October in the department of pathology, Glasgow Royal Infirmary, on the biochemistry of endocrine neoplasms. Professor Engel, who is 58, graduated B.S. at Harvard College before beginning his career in research at Columbia University, where he obtained a Ph.D. in 1936. In the same year, after work at the Federal Polytechnic Institute, Zurich, he came to Britain as guest investigator at the Royal Cancer Hospital, London, under Professor J. W. Cook. He returned to the United States as John D. Archibald Fellow and Instructor in Medicine, Johns Hopkins University, and was then appointed instructor in biochemistry, Mayo Foundation for Medical Education and Research. After service in the Army during the second world war he returned to Harvard as tutor in biochemical sciences, and was later appointed assistant professor of biological chemistry at the Massachusetts General Hospital. He became associate professor of biological chemistry, Harvard University, in 1958, and in 1959 Permanent Faculty Fellow of the American Cancer Society. In 1960 he had a period of study at the Chester Beatty Research Institute and the radiotherapy department, Royal Marsden Hospital, London.

International Federation of Surgical Colleges

The International Federation of Surgical Colleges held its annual meeting in Vienna on 4 to 6 September in association with the International Society of Surgery. Professor J. F. Nuboer (Holland) acted as president in the absence of Professor J. Englebert Dunphy (U.S.A.), president, owing to illness. Professor J-L. Lortat-Jacob (France) was re-elected to the executive committee, and Professor Erik Husfeldt (Denmark) was elected chairman of the committee on surgical missions in succession to Professor Carl Semb (Norway). The council welcomed two new member-institutions to the International Federation, the Czechoslovak Medical Society J. E. Purkyne and the Association of Surgeons and Physicians of Malta. There are now 40 national colleges or associations within the Federation. During the year a meeting was held at Colorado Springs, at which particular interest was expressed in international collaboration on problems of traumatic shock. The next meeting of the Federation will be held in Jerusalem, where the hosts will be the Israel Surgical Society.

Order of St. John of Jerusalem

Those recently appointed to, or promoted in, the Most Venerable Order of the Hospital of St. John of Jerusalem include the following members of the medical profession :

As Commander (Brother) : Dr. W. Bain. *As Associate Commanders (Brothers)* : Drs. Kwong Lam Loh, D Paton, and G. B. Robson. *As Officers (Brothers)* : Professor A. J. Craig and Dr. J. Saliba. *As Associate Officer (Brother)* : Dr. W. S. Norton. *As Serving Brothers* : Drs. H. F. Cowper-Johnson, Z. Wisinger, D. Wyndham Evans, W. McIntosh, N. Shlosberg, P. Cassar, and J. F. Cremona.

Postgraduate Medical Education

Dr. J. O. F. Davies, senior administrative medical officer of the Oxford Regional Hospital Board, has been appointed medical secretary to the Central Committee on Postgraduate Medical Education (see *B.M.J.*, 24 June, p. 833). He will be taking up his appointment in October.

William Russ Pugh

In 1847 Dr. W. R. Pugh administered ether to two patients at St. John's Hospital, Launceston, Tasmania. He was the first man to administer an anaesthetic for a surgical operation in Australia. Dr. Pugh, who was a graduate of the Faculty of Physicians and Surgeons of Glasgow and of the Royal Colleges of Edinburgh, died in England in 1897 and was buried at Brighton. The grave and monument are now in poor repair. The Association of Anaesthetists of Great Britain and Ireland and the Australian Society of Anaesthetists have each contributed £25 to a restoration fund. Other contributions should be sent to the honorary treasurer of the Association of Anaesthetists, Royal College of Surgeons, Lincoln's Inn Fields, London W.C.2.

S.R.C. Support for Biological Research

Support of university research in biology by the Science Research Council has increased more rapidly than in any other sector except technology, the Council states in its annual report (H.M.S.O., 6s. 9d.). Research grants current at the end of March totalled over £2m. There were 645 research students, 52 advanced course students, and 46 research fellows. In 1966–7 about 200 new grants to a value of just over £1m. were approved. Awards are made on the advice of the Biology Committee, one of the 10 committees of the university science and technology board of the Council. Besides considering applications for grants the committee seeks out areas of special promise for examination and support. The first selected are industrial biology, regulation of cell activities, and neurobiology. In its report the Council says that the support it will be able to give to university research in the next few years will not match the rate at which requests have been growing. Support will have to be more selective.

Fellowships in Clinical Pharmacology

Applications are invited by Merck Sharp & Dohme Ltd. for international fellowships in clinical pharmacology for 1968. The fellowships are awarded for study in the United States for periods of up to two years. They are open to candidates who have completed the medical curriculum at an accredited school of medicine and are preparing for a career in teaching and research in clinical pharmacology. Further information can be obtained from the Medical Division, Merck Sharp & Dohme Ltd., Hoddesdon, Hertfordshire. The closing date for applications is 1 November.

Postgraduate Tropical Medical Centre

The International College of Tropical Medicine has published its first (September) newsletter. As already noted (see *B.M.J.*, 1966, 23 July, p. 248), it plans to establish in a tropical environment a major centre, including a teaching hospital, research institute, and a school of tropical preventive and social medicine. Professor T. A. LAMBO, dean of the medical faculty at the University of Ibadan, has been elected the first president. The inaugural meeting will be held from 5 to 7 March 1968 at Dakar, Senegal, West Africa.

British Society of the History of Medicine

At the congress held on 6 to 9 September at the University of Sussex, Brighton, Dr. W. S. C. COPEMAN was installed president of the British Society of the History of Medicine in succession to Dr. DOUGLAS GUTHRIE. LORD COHEN OF BIRKENHEAD was nominated president-elect.

T.V. Award for Medical Film

The programme on osteoporosis in the B.B.C. television series "Medicine Today" (see *B.M.J.*, 29 April, p. 295) was given an award at the international festival of medical television education held earlier this month at the University of Western Ontario, London, Canada. The festival was restricted to films designed to aid the continuing education of doctors.

Church Service for Doctors

A service for doctors will be held in All Souls Church, Langham Place, London W.1, on Sunday, 8 October, at 11 a.m. Sir ROBERT DREW and Mr. D. F. ELLISON NASH will read the lessons. Doctors who wish to reserve seats for themselves and members of their families should apply for tickets to the Church Secretary, 2 All Souls Place, London W.1. A buffet lunch will be available at the Royal Society of Medicine after the service at 15s. a head (7s. 6d. for children aged 14 and under). Applications for tickets should be accompanied by remittance.

People in the News

▶ Mr. T. A. CASEY, M.Ch., F.R.C.S., D.O., has been appointed to the corneo-plastic unit and regional eye bank at the Queen Victoria Hospital, East Grinstead, in succession to the late Sir Benjamin Rycroft. The scope and character of the specialized work at this unit will remain unchanged.

Grants and Awards

The British Empire Cancer Campaign for Research has made a grant of £3,100 to Dr. W. R. GREIG, of the University Department of Medicine, Royal Infirmary, Glasgow, for the purchase of equipment to study cell proliferation in the thyroid gland.

Coming Events

King Edward's Hospital Fund for London.—Exhibition, "The Patient in the Community," Hospital Centre, 24 Nutford Place, London W.1. From 25 September, 9.30 a.m. to 5.30 p.m., Monday to Friday.

Chartered Society of Physiotherapy.—Annual Congress, 30 September, Hotel New Ambassadors, London W.C.1.

British Medical Association.—Introductory course on use of computers in medicine, 12 October, Manchester. Details and forms of application from Assistant Secretary, British Medical Association, c/o North West Regional Office, Boyd House, Upper Park Road, Victoria Park, Manchester 14.

University College Hospital Old Students' Association.—Symposium, "The Investigation of Renal Disease," 19 October, 2 p.m., followed by annual general meeting and sherry party. Annual dinner, 20 October, Savoy Hotel, 7 p.m. for 8 p.m. Application for tickets, with remittance £2 5s. a head, to Honorary Secretary, Old Students' Association, University College Hospital Medical School, London W.C.1. Cheques should be made payable to "U.C.H. Dinner Fund."

Societies and Lectures

For attending lectures marked ● a fee is charged or a ticket is required. Applications should be made first to the institution concerned.

Monday, 25 September

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 5.30 p.m., clinical meeting.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY.—5.30 p.m., combined staff consultation clinical meeting.

KINGSTON-UPON-THAMES MEDICAL CENTRE.—5.15 p.m., slide seminar by Dr. M. E. A. Powell: Liver.●

Tuesday, 26 September

INSTITUTE OF CHILD HEALTH.—At Kennedy Lecture Theatre, 5.30 p.m., Dr. D. G. Freedman (Chicago): Longitudinal Studies of Twins.

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Chelsea Hospital for Women, 2 p.m., Dr. K. A. Newton: Chemotherapy.●

ROYAL STATISTICAL SOCIETY: MEDICAL SECTION.—At Manson Theatre, London School of Hygiene and Tropical Medicine, 5 p.m., Dr. P. M. Fraser: Use of the Computer in the Classification and Diagnosis of Liver Disease.

WHIPPS CROSS HOSPITAL.—At Medical Education Centre, 1 p.m., clinical meeting.

Wednesday, 27 September

CHELMSFORD MEDICAL EDUCATION AND RESEARCH TRUST.—At Chelmsford Medical Academic Unit, London Road (grounds of Chelmsford and Essex Hospital), 12 noon, surgical meeting.

ROYAL COLLEGE OF SURGEONS OF ENGLAND—6 p.m., Robert Jones lecture by Mr. A. L. Eyre-Brook: Some Aspects of Congenital Dysplasia of the Hip.

ROYAL FREE HOSPITAL—5.15 p.m., Dr. J. B. L. Howell: The Breathless Patient.

STOKE MANDEVILLE HOSPITAL.—6 p.m., Dr. C. S. Pitcher: Haemorrhagic Disorders.

Thursday, 28 September

INSTITUTE OF OBSTETRICS AND GYNAECOLOGY.—At Queen Charlotte's Hospital, 11.15 a.m., discussion: Erythroblastosis. Speaker, Mr. A. C. H. Walker.●

KINGSTON-UPON-THAMES MEDICAL CENTRE.—2.30 p.m., (1) film: Marrow Puncture; (2) Dr. F. R. Ellis: Indications for Marrow Puncture and Some Typical Appearances.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS.—4 p.m., William Meredith Fletcher Shaw memorial lecture by Dr. E. A. Gerrard: The Patient as an Individual.●

Friday, 29 September

BROOK GENERAL HOSPITAL.—At Postgraduate Medical Centre, 2 p.m., lecture demonstration by Dr. P. Forgacs: Respiratory Function Tests in Clinical Practice.

KENT POSTGRADUATE MEDICAL CENTRE AT CANTERBURY.—At Kent and Canterbury Hospital, 8.30 p.m., inaugural lecture by Mr. D. W. C. Northfield: Differential Diagnosis of Intracranial Tumours in the Adult.●

Deaths

Bentley.—On 10 September 1967, suddenly, Francis Joseph Bentley, M.D., F.R.C.P., D.P.H.

Corrections

The Newcastle Regional Hospital Board have corrected a recent appointment issued by them and published (29 July, p. 318). E. T. Young, M.B., M.R.C.P. (consultant in geriatrics, Wansbeck), should read (consultant physician, Wansbeck).

The University of Glasgow wish to point out that in anouncing the award of M.D. to Dr. Jean R. Nairn (22 July, p. 253) they omitted to say that it was "with commendation."

In our issue of 2 September 1967, page 606, the publisher of *The Medical Annual*, 1966, was inadvertently given as Longmans, Green, of London. This book was published by John Wright & Sons, of Bristol.

New Issues of Specialist Journals

Obtainable from the Publishing Manager, B.M.A. House, Tavistock Square, London W.C.1.

BRITISH JOURNAL OF MEDICAL EDUCATION

Contents of the September issue are as follows:

Editorial.
Association for the Study of Medical Education.
The General Medical Council's Recommendations as to Basic Medical Education 1967:
  1. The Views of a General Practitioner. Ronald Gibson.
  2. The Views of a Teacher of Physiology. K. B. Roberts.
  3. The Views of a Teacher of Medicine. G. A. Smart.
The Role of the University in the Future. Bror Rexed.
Factors Influencing the Development of a Curriculum. V. Ramalingaswami.
The Objective Examination in the Evaluation of Medical Students. H. J. Walton and J. Drewery.
Evaluative Study of a Preceptorship Programme in General Practice for Senior Medical Students. Moshe Prywes, Moshe Sarrell, and Yair Yodfat.
Role of the Peripheral Hospital in Postgraduate Anaesthetic Training. J. D. Hill.
Teaching of Diagnostic Radiology in Britain and the United States. J. H. Middlemiss.
A British View of the American Surgical Residency. Adolf Singer.
Teaching Medical Ethics—Empirical or Rational? I. B. Pless.
Teaching Public Health in the Faculty of Medicine, University of Khartoum, Sudan. Mamoun Yousif.
On Evaluating the Success of Teaching. An Inquiry in London University Medical and Dental Schools. Ruth M. Beard.
Glasgow Conference on Specialist Training. James H. Hutchison.
Book Reviews. News and Notices.

Volume 1, No. 4. Yearly subscription (4 numbers) £3 3s., abroad £3 10s.

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON W.C.1. TELEPHONE: 01-387 4499 TELEGRAMS: *Aitiology, London W.C.1.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.
Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs.
ADVERTISEMENT AND SUBSCRIPTION ORDERS should be addressed to The Manager at B.M.A. House, London, or at 415 Bourke Street, Melbourne, Victoria, Australia.
MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the British Medical Association, B.M.A. House, London, or to the Scottish Secretary, B.M.A. Scottish Office, Drumsheugh Gardens, Edinburgh.

BRITISH MEDICAL JOURNAL

Pointers

Facial Palsy: Discussion of the aetiology and the case against surgical treatment (p. 815).

Alcohol and Motoring: Leading article on this page. Report on discrepancies between different methods of testing blood and urine (p. 819). Letter at p. 861. Police tests in hospital (*Supplement*, p. 142).

Tropical Splenomegaly: Patients with idiopathic "big spleen disease" in Uganda treated by splenectomy were symptomatically and haematologically much improved (p. 823).

Plasma Therapy in Haemophilia: Prompt infusion of plasma can reduce duration of incapacity and incidence of new deformities of joints, but there is widespread ignorance about this method of treatment (p. 828). Plasma prophylaxis in Christmas disease (p. 864).

Management of Haematemesis: Gastric cooling as an adjunct to usual conservative treatment in severe cases conferred no extra benefit (p. 831).

Effects of Folate Deficiency: There is a positive correlation between C.S.F. and serum folate activity, but mean C.S.F. folate levels in patients with various neurological diseases were the same as in a control group, except drug-treated epileptic patients who had a high proportion of subnormal folate levels (p. 834).

Amputation in Atherosclerosis: Results using Gritti–Stokes amputation compare very favourably with other techniques and immediate fitting of prostheses has been successful (p. 837).

Brief Case Reports: Myasthenia gravis in two generations of one family (p. 839). Oleogranuloma following self-injection of petroleum jelly (p. 840). Pituitary dwarf attaining age of 77 years before requiring treatment (p. 842). Pyloric obstruction produced by adenomyoma of stomach (p. 843). Spontaneous rupture of uterus at 22 weeks' gestation (p. 844). Compression of spinal cord complicating diaphysial aclasia (p. 844).

Immunization: Schedules (p. 846).

Polycythaemia with Aortic Stenosis: Clinicopathological Conference at the Royal Postgraduate Medical School (p. 848).

"Swabs Correct?": Use of a fixed number of polyurethane sponges in place of conventional gauze swabs could make the swab count an anachronism (p. 852).

Appointment System: Effect of demands for urgent treatment (p. 856).

Whom to Resuscitate: Neasden memorandum and official comment (p. 858). Letter (p. 861) and leader (p. 814).

Hospital Junior Staffs Group Council: Report of meeting, *Supplement*, p. 139.

Organization Committee: *Supplement*, p. 141.

Alcohol and the Law

On 9 October the Road Safety Act[1] comes into operation, making it an offence for a motorist to drive, attempt to drive, or be in charge of a vehicle if his blood alcohol level is over 80 mg./100 ml. or his urine alcohol is over 107 mg./100 ml. This brings Britain into line with the many other countries which have a statutory level for blood alcohol, and reflects the widespread acceptance of the need for measures to reduce the numbers of deaths and injuries caused by road accidents. At p. 819 of this week's *B.M.J.* Professor J. P. Payne and his colleagues comment on the interpretation of tests for alcohol in blood and urine and on the different techniques that may be used.

Payne and his colleagues have confirmed that gas chromatography with an internal integrator—the technique that will be used in police laboratories throughout Britain—is a reliable method of estimating the alcohol content of small volumes of fluid, but they report disturbing discrepancies in the values obtained when different methods of sampling blood were used. When capillary tubes were used the alcohol content of the blood was found to be considerably lower than that of corresponding venous blood. Capillary blood samples from volunteers were analysed in a number of centres (with the co-operation of the Home Office) and wide discrepancies were found in the values obtained from samples in capillary tubes. When the blood was collected in plastic pots more consistent results were obtained, and the levels were closer to those found in venous blood, but there was still disagreement. It seems that the source of these errors is the method used to obtain the sample rather than the technique of analysis. If the operation of the Act is to be fair the Home Office should draw up a protocol for the taking of samples of blood and its subsequent handling which reduces the risk of error to a minimum.

Estimates of the level of alcohol in the urine were the first scientific tests to be used widely in Britain in prosecutions of motorists alleged to have been drinking. Police and police doctors have become familiar with the tests, which have the advantage that it is usually easy to obtain large volumes of urine from the suspect. However, it has long been recognized[2] that the relation of the level of alcohol in the urine to that in the blood is not constant and is influenced by several factors, some known and some unknown. In its report *The Drinking Driver*[3] in 1965 the B.M.A. special committee recommended that blood and breath tests should be used in preference to urine under the law prevailing at that time, and in commenting on the Road Safety Bill during its passage through Parliament the B.M.A. Council stated[4] that it "would prefer samples of blood to be taken in every case."

No doubt recognizing that there could be arguments in court about the conversion factor, the Government has specified 107 mg./100 ml. as the critical level for alcohol in the urine (a second specimen taken one hour after the first). Defence counsel will not be able to challenge the relationship of this level to the blood level of 80 mg./100 ml. Payne

and his co-workers report the results of estimations of the level of alcohol in the blood and urine of motorists suspected of offences under the present law. When the ratio of blood to urine levels was calculated the range of the factor was from about 1 to about 2.5—much wider than the range found in laboratory experiments on volunteers. So a motorist with alcohol in his body close to the levels laid down in the Act might have a blood level below the limit and a urine level above it or vice versa. Analysis of these results by a professional gambler would lead him to advise suspects to opt for the blood test—but should such advice need to be given? If the Act is to be seen to be fair in its application urine samples should be used as little as possible and if possible not used at all.

Legislation to discourage driving under the influence of alcohol is welcome, and most drivers will want to co-operate. Press comment suggesting that the level of 80 mg./100 ml. is the upper limit for safe driving is dangerous. The ability of most drivers to drive properly is impaired when the blood alcohol is well below this level. Doctors asked for advice by their patients should tell them that they should not drive after drinking. Patients who find this impossible should be told to stick to the "rule of three"—three half pints of ordinary beer or three single-measure whiskies—but those not used to alcohol should take no alcohol before driving. No alcohol should be taken before driving if the stomach is empty; and it is never safe for a person to drive if he feels he has been affected by alcohol. Doctors should also warn their patients against taking alcohol if they are taking drugs such as barbiturates or tranquillizers.

The publicity campaign by the Ministry of Transport is designed to produce better attitudes to drinking and driving. A change in social habits of drivers is more likely if the public is convinced that the element of luck in the application of the new law has been eliminated. This will be the case only if all prosecutions are based on blood samples taken by a uniform procedure which eliminates chance errors.

Aspirin and Gastric Bleeding

Aspirin was first shown to damage the gastric mucosa 30 years ago,[1] and histological[2] and physiological studies[3] have confirmed that this is a direct toxic effect. Until recently gastric erosions caused by aspirin were thought to result from particles of the drug "burning" holes in the mucosa. However, biochemical and cytological investigations[4] have now shown that soluble aspirin dispersed in saline causes exfoliation of the surface epithelial cells of the stomach within five minutes of ingestion, and D. N. Croft[5] has suggested that this may initiate the formation of haemorrhagic erosions.

The clinical importance of the toxicity of aspirin must be assessed in the light of the huge consumption of the drug in Britain and the two ways in which it is used. Firstly, aspirin is prescribed for the treatment of chronic rheumatic disorders in doses of 1 g. four times a day for weeks or months; and, secondly, a large proportion of the population take it, with or without medical supervision, as an occasional analgesic or antipyretic.

Repeated ingestion of soluble aspirin in the dosage used to treat rheumatoid arthritis has been shown by P. H. N. Wood and others[6–8] to cause chronic gastrointestinal bleeding which can lead occasionally to iron deficiency anaemia.[9] Patients taking three aspirin tablets four times a day were studied by Croft and Wood,[10] who found that of 218 investigated 67% lost 3 ml. to 10 ml. of blood each day. A minority of patients (22%) were insusceptible, losing less than 3 ml. a day, but 11% lost more than 10 ml. daily. These workers also found gastric erosions in specimens removed at partial gastrectomy from subjects who had taken repeated doses of aspirin for a few days before elective surgery. This suggests that chronic bleeding due to aspirin can occur from erosions.

The role of aspirin in the pathogenesis of haematemesis and melaena remains controversial, but there is good evidence for an association between acute bleeding from erosions and the use of aspirin as an occasional analgesic.[11–13] This relationship does not appear to be influenced by the age of the patient or by the frequency of ingestion of aspirin. As aspirin is such a commonly used drug acute bleeding is clearly a rare complication, and carefully controlled studies are required to demonstrate the association. In populations where other factors such as alcohol are more important any role that aspirin has in initiating the bleeding may be obscured. D. J. Parry and Wood have recently[14] described their findings in a careful study of 637 patients admitted consecutively during fifteen months to two medical wards of a hospital in south-east England. The patients were questioned carefully about their ingestion of aspirin during the week before admission. Of 542 patients admitted for complaints other than gastro-intestinal haemorrhage one-third had consumed aspirin—a surprisingly high proportion. The 95 patients admitted with haematemesis and melaena were examined by gastroscopy and if no lesion was found a barium meal was performed. Of those who had a chronic gastric or duodenal ulcer 51% had taken aspirin, which was little higher than the control group. The remarkable finding in this study was that of the 35 patients admitted with acute bleeding who had either an acute gastric erosion or in whom no lesion was found (implying a small acute lesion) no fewer than 33 (94%) had taken aspirin

during the previous week. The likelihood of this finding being due to chance alone was less than one in a thousand. These observations support other evidence[13 15] that aspirin causes acute bleeding from gastric erosions. In this series at least one-third of the acute bleeds appeared to have been initiated by aspirin.

Is it possible to define a population at risk ? Croft[6 10 16] has suggested that resistance to the effect of aspirin in inducing occult bleeding may be due to a higher than normal rate of turnover or replacement of the surface epithelial cells of the stomach. There is no clear answer, however, for acute episodes of bleeding. Parry and Wood investigated the problem by studying 39 of their patients in whom there was strong circumstantial evidence that aspirin had precipitated the haemorrhage. Once the patients had recovered they were given aspirin continuously for a few days and occult blood loss was measured. The subjects were found to be no more susceptible to aspirin, as measured by this test, than was a control group. This suggests that aspirin initiates acute bleeding only at times and under circumstances when the gastric mucosa is temporarily susceptible. It "takes the mucosa by surprise." The factors responsible for enhanced susceptibility require investigation, and may include alterations in the turnover or healing power of atrophic areas of gastric mucosa.

What should the clinician's attitude be to aspirin ? When given continuously it is an invaluable treatment for rheumatoid arthritis and other chronic rheumatic conditions. Under these circumstances iron deficiency anaemia occurs occasionally and patients may need treatment with iron. But there is at present no method of predicting the circumstances in which a patient may be susceptible to the risk of acute bleeding. Those who have had an episode of bleeding should be warned to avoid aspirin. Paracetamol, which does not cause bleeding,[17] is a satisfactory analgesic for occasional use and in intermittent doses it is unlikely to have any other deleterious effects. Surely the time has come to advise patients to keep this drug, rather than aspirin, in the medicine cupboard.

Operations on the Gall Bladder

Modern biliary surgery started 100 years ago when J. S. Bobbs[1] performed the first cholecystotomy, though it was a completely unplanned procedure—the preoperative diagnosis was an ovarian cyst. Despite this century of experience there is still controversy about some aspects of surgery in this region, particularly at the two ends of the spectrum of disease of the gall bladder—symptomless gall stones and acute cholecystitis. Recent careful studies have provided factual information[2-4] to add to the mass of clinical impressions on these topics.

Gall stones are extremely common and their frequency has been well shown by several necropsy studies. Thus G. Horn[2] reviewed some 5,000 necropsies on adults in Birmingham. The overall incidence of biliary stones was found to be 5.8% in males and 13.2% in females. The incidence increased as age advanced so that about 20% of subjects over the age of 70 had calculi. The sex difference was much less definite in the older age groups. M. W. Comfort and his colleagues[3] studied 112 patients in whom stones were discovered incidentally in the course of *x*-ray investigations and found that over a 20-year period half the patients had developed symptoms due to the stones. Recently A. Wenckert and B. Robertson[4] described a similar study in Malmo, Sweden. There were 781 patients with gall stones demonstrated cholecystographically who had neither operation nor complications within the first year of the *x*-ray examination. They were then followed up for a period of 11 years. Half the patients remained symptom-free or had had only mild symptoms. One-third suffered attacks of biliary colic, and many of these were submitted to elective operation. In the remaining one-sixth serious complications occurred, including acute cholecystitis, obstructive jaundice, pancreatitis, and, in three cases, malignant change in the gall bladder. The incidence of complications was higher in patients who were 60 years of age or more, but there was no sex difference. These complications of gall stones are serious, painful conditions, and the conclusion to be drawn is that when gall stones are discovered incidentally in otherwise healthy patients elective surgery should be advised.

Acute cholecystitis is usually treated conservatively in Britain, emergency operation being reserved for patients in whom the diagnosis is in doubt or where the signs indicate progression of the inflammatory process. Elective cholecystectomy is usually advised some three months after the acute episode. The risk of perforation of the inflamed gall bladder is small. H. Ellis and K. Cronin,[5] for example, reviewed 795 patients admitted to the Radcliffe Infirmary, Oxford, with acute cholecystitis. Eleven (1.4%) had bile peritonitis, but only one of these had developed the condition while in hospital, on the seventh day of an undiagnosed illness. The mortality and morbidity rates for operations performed in the acute phase of cholecystitis are usually higher than those in elective surgery. K. A. Meyer and his colleagues,[7] surveying a large series of cases in the department of surgery of the North Western University Medical School, Chicago, found the overall death rate in their series with acute cholecystitis to be 4.5% as compared with 1.1% in those who underwent surgery for chronic cholecystitis. Indeed the mortality rate for cholecystectomy alone when carried out for acute cholecystitis was higher than that for those patients operated upon for chronic cholecystitis even when the latter group had a common duct exploration performed at the same time. Similar results have been obtained by other workers. C. G. McEachern and R. E. Sullivan[7] reported a mortality rate of 5.8% in 155 patients who had emergency cholecystectomy performed for acute cholecystitis, though it should be noted that five of their nine patients who died had perforated gall bladders, and A. W. Hargreaves[8] has recently reported 55 cases treated by emergency surgery at the Salford Royal Hospital; there were three deaths and nine cases of wound infection.

The advocates of early surgery in the acute phase of cholecystitis argue that the operation is easily performed (owing to the presence of inflammatory oedema), the risk of bile duct or vascular damage is small in experienced hands, and readmission to hospital is avoided. Moreover, the later elective operation is often made difficult by the development of dense adhesions around the gall bladder and its ducts.

Like most controversial topics in medicine, the truth probably lies between the two schools of thought. In the early acute case—roughly within the first 48 hours—operation is indeed quite simple and there is no contraindication to its performance in an otherwise fit patient provided a skilled surgeon is available and that there are full facilities for operative cholangiography. Surgery is also indicated if the gall bladder has perforated before admission or if the disease does not settle with conservative treatment, when a cholecystotomy is usually necessary. However, in the patient whose acute attack has been in progress for some days, or who is grossly fat or a poor risk or who is in a hospital where adequate operative facilities are not available, a conservative regimen is the wiser course—better a living problem than a dead certainty.

Nonbacterial Vegetations on the Heart Valves

Nonbacterial vegetations are seen on the heart valves in rheumatic carditis and the Libman–Sacks endocarditis of systemic lupus erythematosus.[1] They consist of platelet aggregates covered with fibrin, and they arise on areas of inflammation and necrosis in the valve substance. Vegetations may also occur on valves that are apparently normal in the condition of nonbacterial thrombotic endocarditis—sometimes called terminal endocarditis because it is usually considered a terminal phenomenon of little clinical significance.[2] [3] In one series it was noted in 78 of 18,486 consecutive necropsies, and in 11 cases there was systemic embolism with infarction, which was in some instances the immediate cause of death,[4] an indication that the condition is not always terminal. It is specially prone to complicate widespread cancer,[5] [6] but it may occur in many other conditions and may be the first indication of a systemic disease.[4]

The valves affected are usually the mitral and the aortic, which show slight degenerative changes in the collagen framework without a cellular reaction. It has been suggested that altered collagen forms the bulk of the vegetations,[7] but they are in fact thrombi developing on slightly abnormal valves.[5] It is likely that in some cases the clotting time of the blood is decreased.[6] The vegetations may become organized, and it is possible that the common Lambl's excrescences, small filiform processes found on the valves of elderly people, have their origin in minute thrombi of this nature.[8] [9]

Nonbacterial valvular vegetations can be produced experimentally in animals by creating an arteriovenous fistula between the femoral or iliac arteries and veins or between the aorta and the inferior vena cava.[10] These vegetations are apt to become infected spontaneously, and if bacteria are injected intravenously a bacterial endocarditis invariably results.[11] It is possible that the cardiovascular stress produced as a result of the shunt leads to minor valve damage which predisposes to thrombosis and bacterial infection. Recently K. Nakao and A. A. Angrist have studied the pathogenesis of these valvular lesions in rats in which arteriovenous fistulae had been produced between the aorta and the inferior vena cava below the renal vessels.[12] They found that the first changes occurred in the loose connective tissue underneath the endothelial basement membrane. There was an oedematous dissociation of the collagen fibres, due probably to a biochemical change in the ground substance. At the site of these lesions there was a patchy denudation of endothelial cells, and platelet aggregation tended to occur on the fibrinoid material consisting of collagen fibres, fibrin, and acid mucopolysaccharide. A constant feature of this type of experiment is hyperplasia of the adrenals. Its cause is unknown, but it has been suggested that excessive production of glucocorticoids plays a part in the connective tissue changes in the valves.[13] [14]

While this experimental work seems to have no immediate application to man, it serves to throw light on the pathogenesis of both nonbacterial thrombotic endocarditis and the bacterial variety, which is a serious complication of pre-existing valvular disease and congenital heart disease. It is interesting that subacute bacterial endocarditis is not uncommon in the elderly, and that in the majority of cases there is no gross valvular disease to account for its localization.[15] [16] It is likely that these "virgin valves"[15] are the seat of nonbacterial thrombotic endocarditis which subsequently becomes infected. It is evident that this variety of vegetation is not necessarily a terminal event or of little clinical importance. In a study of its pathogenesis may lie a greater understanding of the mechanism of bacterial localization in the infective type of endocarditis.

Acute Necrotizing Encephalitis

"Encephalitis" is one of the most unsatisfactory clinical diagnoses in neurology. If the illness is mild the patient recovers and the diagnosis is rarely firmly established, while in those seriously ill the diagnosis is often incorrect and if too readily made may mask until too late some lesion such as a tumour or an abscess which may have required urgent surgical treatment. Several devastating affections of the brain which are apparently encephalitic have been classified pathologically, but clinical diagnosis is very difficult and in few of these conditions is either the aetiology or the treatment clear. However, one condition—acute necrotizing encephalitis—is being clinically recognized more frequently by neurologists and neurosurgeons, and evidence is growing that many of these cases are due to the herpes simplex virus. J. Hume Adams and W. Bryan Jennett[1] have recently described eight typical cases and list most of the published accounts. The earlier literature is reviewed by W. Haymaker and his colleagues[2] and by L. van Bogaert and his colleagues.[3]

The disease occurs at all ages and the sexes are equally affected. There may be a prodromal illness with general malaise, pyrexia, and possibly upper respiratory infection, and then over two or three days the patient becomes confused and develops headache of moderate severity, high pyrexia, and slight neck stiffness. Convulsions, which may be focal, often occur and a moderate hemiparesis may develop at the same time or later. The picture is that of a rapidly expanding cerebral lesion, though clinical localization is sometimes difficult and the systemic signs are unusual. The cerebrospinal fluid has a raised cell count (60 to 300 leucocytes/cu. mm.), perhaps a number of red cells, and a high protein but normal sugar content. If the centrifuged deposit is stained and examined the cells may be found to be atypical mononuclears belonging to the plasmacyte series, some showing mitotic figures, the picture suggesting an acute inflammatory process. Electroencephalography shows diffuse slow wave abnormalities often with multiple sharp foci, though the tracing is not diagnostic in any way. A normal E.E.G. virtually excludes the condition. Echo-encephalography may show a non-specific shift of mid-line structures, and arteriography or ventriculography may also suggest a unilateral expanding lesion in one or other temporal lobe. If an exploratory biopsy is carried out, however, necrotic brain only will be found, but specimens of brain taken at this time can be examined for the presence of the herpes simplex virus, and the diagnosis can be confirmed by the demonstration of a rising titre of herpes antibody in the blood.

The mortality rate has so far been very high, but measures aimed at reducing intracranial pressure combined with the use of corticosteroids and antibiotics have apparently saved several patients' lives though leaving some with serious neurological deficits.

The condition can often be recognized macroscopically at necropsy by the markedly asymmetrical oedema and softening of the brain, affecting principally the temporal lobes and posterior orbital gyri, scattered through which are multiple haemorrhagic foci, the lesions often extending across the corpus callosum. Histology shows general changes of encephalitis, but most striking is the selective necrosis in the grey matter and subjacent white matter of the temporal lobes, the orbital and cingulate gyri, and the insula. Occasionally intranuclear inclusions of herpes type may be shown, and when these have been studied by electron microscopy they have been considered confirmatory of the presence of herpes simplex virus.

Whether this condition is due to direct virus invasion or represents yet another antigen-antibody reaction, and whether herpes virus is the only cause or the only one so far demonstrated are all points as yet uncertain. Nevertheless it is important to recognize the existence of the disease not just as a pathological curiosity but as a serious and not too uncommon condition capable of being diagnosed by full neurological and neurosurgical investigation and offering a chance of successful treatment if the effects of the high intracranial pressure can be combated. Herpes simplex encephalitis was at one time too readily diagnosed and fell somewhat out of favour when it was realized that there are several diseases characterized by an encephalopathy with inclusions. Now perhaps it is coming back into prominence in its correct role.

Increase in Stabbing

Stab wounds differ from other penetrating injuries by being in most cases inflicted deliberately and with malice, but they share with them the possibility of causing deep and serious damage that may go unrecognized until complications develop. For doctors working in accident and emergency departments it is wise to regard all puncture wounds with deep suspicion until the amount of damage done has been established beyond doubt. Deliberate stabbing, accidental stabbing, and falling or being thrown against sharp and sometimes blunt projections[1] have it in common that penetration is forcible, and what the victim feels at the time rarely gives any indication of the depth of penetration or the damage caused. Far from feeling " a stabbing pain," many stabbed persons are aware of no more than a blow, and some do not know that they have suffered injury until they are found to be bleeding.

As much detail as possible should be sought about the direction and force of the blow, about the victim's posture, and about any feelings such as numbness, tingling, and loss of power at the moment of injury. It is particularly important that unconscious persons and victims of assault be examined thoroughly after being stripped because stab wounds may be widespread as well as multiple, and those overlying important organs are not necessarily the most important ones. Useful information may come from any discharge from a wound and from *x*-ray examination.

When exploration is necessary it should be undertaken as a formal surgical procedure, with whatever facilities may be needed to deal with the complications of the wound concerned. Bleeding is the most dangerous.[2 3] Even when there is no evidence of deeper damage, it is generally wise to explore wounds near large blood vessels and wounds of the face and eyelids[4] and of the buttocks and perineum. Nevertheless, it can take a good deal of experience to know not only when to explore but also how to explore a wound that may be small and apparently superficial and harmless. Probing can be a dangerously inadequate test of the depth and importance of a penetrating wound. Senior surgeons should do all they can to pass on their experience to their juniors, which may mean holding themselves in readiness to advise, supervise, or operate in such cases, which are likely to occur during the evenings of the weekend.

Stab wounds of the trunk penetrate the various sections of body cavity less often than might be supposed ; N. R. Batey and G. C. MacBain[5] found that only half did. In the chest emergency thoracotomy is necessary to deal with severe bleeding, a torn bronchus or trachea, and perforation of the gullet. Stab wounds of the lower part of the chest may penetrate the diaphragm and abdominal viscera. Otherwise the active treatment required is usually no more than to drain a pneumothorax, which may be valvular, a haemothorax, and, occasionally, a haemopericardium.

The general rule that stab wounds of the abdomen should be explored needs revision in view of the fact that about half the victims have been found to have suffered no damage to viscera.[5-7] Even when exploration is carried out only in those patients with general or local evidence of serious damage a few bellies have been opened unnecessarily, as it turned out.[6 7] Coeliotomy is unnecessary when a radio-opaque liquid injected through a catheter fitting snugly into the wound does not enter the peritoneal cavity,[8 9] but the further refinement of peritoneal lavage[2] is of value if the liquid is contaminated by bile or intestinal content or if it comes out clear. If it is blood-stained, only exploration will show whether the blood has come from the abdominal wall or from inside it. To sum up, the surgeon who opens the belly to be on the safe side is less likely to make a serious mistake than the one who practises selective exploration, with whatever tests.

It seems likely that violent and malicious fashion has played a part in the recurrent increase in stabbing,[3 5] which has fortunately carried a mortality rate of no more than 10–15%. The heavy sentences that subdued razor slashing in Glasgow[5] and deliberate stabbing of the spinal cord in South Africa[10] might act as a deterrent again.

Senescence

Is there a single cause of ageing, or are there a number of independent ageing processes? The question, asked once more in the latest annual report of the Medical Research Council,[1] is important because it bears on prevention. If the causes of senescence are different in every person control seems unlikely—unless behind the multiplicity of changes there is a further overall process accessible to treatment.

One of the most interesting biological explanations of ageing is the evolutionary and selectionist theory formulated first by J. B. S. Haldane and developed by Sir Peter Medawar. It runs roughly as follows. Once the contribution of an individual to the pool of offspring ceases, so, indirect selection apart, does the power of evolution to select against adverse changes in the individual due to age alone. Indeed, a gene array producing high fertility and vigour in youth but cancer in middle age would be positively selected. In this view ageing is the random accumulation of failures which evolution has failed to suppress.

D. C. Wallace has recently developed this argument further by mathematical studies. The evolution of lifespan is by no means a straightforward business. It is hard to see, for instance, why small birds with a normal wild life of about nine months, a very high random mortality, and early loss of reproductive power should have potential lifespans of nearly 20 years, or why large fish, with 99% of their mortality concentrated in the first few days of life, should have potential lifespans greater still. The general plausibility of the Haldane–Medawar theory remains, however.

Wallace[2] draws from his equations the pessimistic conclusion that, since ageing is a random accumulation of delayed genetic effects, it is unlikely that anything can be done about it: there can be no unitary cause, though there may be consistencies as to which system fails first. This view may be correct, but it is by no means self-evident, particularly in view of the growing body of evidence locating senile deterioration in the store of information in the cell nucleus. In fact if, as Wallace himself agrees, we are dealing with a variety of harmful and accumulating mutations this is in itself an accessible unitary cause, and biochemical geneticists will not share his pessimism. If the stability of the gene can be improved then changes in the individual's genetic composition can be postponed. If this is correct the problem of slowing the process of ageing becomes analogous to that of conservative dentistry, with the conservation of genes substituted for that of teeth. Recent work on antioxidants, antiradiation drugs, lysosomal stability, and other related topics makes it clear that, while it might be difficult to deal with multiple late-acting genetic defects present from birth, loss of information through instability of D.N.A. might well be controllable. There are also rodent experiments which indicate that the "clock" of the lifespan can be considerably slowed by simple calorie restriction. All in all, pessimism over the controllability of ageing derived from mathematical considerations is unlikely to daunt gerontologists in search of a means of tampering with the rate of human decline.

Vital Decision

Not all patients who die should be subjected to attempts at resuscitation. No doctor who himself has had to use modern techniques of resuscitation would suggest otherwise—nor would he be unaware of the distress caused to relatives and other patients in the ward by the failure of a lengthy attempt which should never have been made. Earlier this year we stated[1] that "the close of a long life or an incurable illness should be allowed to occur peacefully." This is in the best tradition of medicine.

To be successful resuscitative measures must be started within a minute or two of cardiac arrest. In hospital the first person on the scene is usually a nurse, who is trained to initiate cardiac massage while medical support is summoned. The doctors who arrive often will not have seen the patient before, and their time will be fully occupied in maintaining oxygenation and the circulation, taking an electrocardiogram, and setting up an infusion to combat the acidosis. This is not a time when anyone can consider the patient's history and diagnosis to decide whether or not resuscitation should be attempted.

So if patients with terminal irreversible disease are not to be resuscitated the individual doctor looking after them must decide this in advance. Nursing and medical staff who may be summoned in an emergency must be in no doubt as to the decision that has been made. The method used at Neasden Hospital (see p. 858) has been the subject of some hysterical and ill-informed comment in the last week. Those unfamiliar with the practical problems find it hard to appreciate that the decision to resuscitate or not must be made before the emergency occurs. Moreover, it must be made known to all concerned. Patients and their relatives need not be alarmed by the recent outcry. The decision is not a difficult one for doctors. Every patient, whatever his age or his disease, should be resuscitated unless the doctor looking after him has no doubt at all that he should be allowed to rest in peace.

Papers and Originals

Facial Paralysis*

HENRY MILLER,† M.D., F.R.C.P.

Brit. med. J., 1967, 3, 815–819

At first sight facial paralysis seems a banal and even uninteresting subject. After all it is a common condition, often of no great clinical importance, and we deal with most of our cases by rule of thumb. In fact, it poses a number of intriguing and unanswered questions in the fields of anatomy, neurophysiology, and pathology. Its systematic consideration covers a wide range of general medicine, and it affords a promising field for research by the subtle techniques of the applied neurophysiologist, as well as by the simpler methods of the clinician.

If there is one particular lesson to be learnt from a review of this subject it concerns the extent to which therapeutic practice depends on personal impression and uncontrolled observation, rather than on any scientific or rational basis. Nowhere is this more evident than in the case of Bell's palsy, which is bound to occupy a good deal of any discussion devoted to the problem of facial paralysis.

An extensive review of the world literature has yielded no single shred of scientifically valid evidence that surgical treatment exerts a favourable influence on the course of this disorder, yet there are surgeons all over the world who profess an almost religious conviction of its efficacy, and who apparently perform an operation of one kind or another on practically every case referred to them. Some such enthusiasm may of course be a spontaneous manifestation of that innate physical energy and *joie de vivre* that so often distinguishes the surgeon from his more debilitated medical colleagues. On the other hand, I do not find it easy to dissociate the repeated and urgent pleas that reverberate through the American literature describing Bell's palsy as a surgical emergency and begging the physician to refer it at once to the nearest otolaryngologist from the special economic conditions of practice in the United States.

I am reminded of a revealing comment of that great medical historian Henry Sigerist, of Johns Hopkins University, 30 years ago. He observed that the treatment of chronic rheumatism in the United States comprised a prolonged series of expensive injections carried out in the physician's office; in the Soviet Union it consisted of a protracted and expensive course of physiotherapy carried out in a trade union nursing-home on the shores of the Black Sea. We have no evidence to show which of these was the more effective routine, or indeed whether either procedure influenced the course of the patient's disease for better or for worse. What this contrast certainly did reveal was the potent influence of social and economic considerations on medical practice in general and our therapeutic habits in particular. Perhaps the slight hint of therapeutic nihilism that our Continental visitors detect in the British approach to the treatment of facial palsy may not be entirely unconnected with the fact that we work in a professional environment where it is necessary neither to ensure the patient's gratitude nor to impress him with the dynamism of our therapeutic approach.

Clinico-anatomical Considerations

The diagrammatic anatomy of the medical neurologist is of course a far cry from the flesh-and-blood anatomy of the surgeon. It is true also that there are many aspects of the finer structure and function of the facial nerve about which we remain woefully ignorant. However, we know enough to allow us to localize anatomical lesions of this particular nerve on the basis of simple clinical examination, an exercise always pleasurable to the neurologist. Here we will first discuss some of the commoner types of facial palsy as they arise from lesions at various sites on the motor pathway.

Supranuclear Lesions

In the first place it must always be remembered that facial paralysis or weakness may be due to a lesion above the nucleus of the nerve, affecting the corticopontine tract at any part of its course. It may present as an isolated facial paralysis due to a cortical or subcortical lesion, or alternatively as part of a hemiparesis in which infarction or tumour has involved the corticopontine and corticospinal fibres where they are more closely packed together in the neighbourhood of the internal capsule, or lower still in the brain stem. The facial paralysis of a corticopontine tract lesion is characterized by sparing of the upper face. It is not infrequent for a neurologist to be called out to see a patient who is believed to have had a stroke and to observe at once the paralysis of the whole face on the one side that enables him to dispense reassurance that there has been no serious cerebral accident and that the patient is suffering from nothing more serious than a simple attack of Bell's palsy. The upper face escapes in corticospinal tract lesions, because the neurones of the facial nucleus that control movement of the upper face receive impulses from both cerebral hemispheres, while the neurones of the facial nucleus that control the movements of the lower face are activated only by impulses reaching them from the opposite hemisphere.

There is another intriguing feature of facial weakness caused by lesions of the upper motor neurone. Sometimes the involuntary movement of the face that occurs on smiling is retained and may be more than usually conspicuous, even though the patient cannot contract the same muscles at the side of the mouth at all on voluntary movement. This may be very striking, and it is of course never encountered in lesions of the lower motor neurone, where the final common pathway is interrupted and the whole face is paralysed for movement of any kind. There is also a less frequent condition in which the converse is observed: voluntary movement of the face is normal, but emotional and involuntary movement paralysed or weak. This also arises from lesions above the nucleus, but not from damage to the corticopontine fibres of the pyramidal tract. The sites of the lesion or lesions that produce this so-called mimetic facial paralysis are uncertain. They are usually at or below the thalamic level. Sometimes at least they are in the corpus striatum and may be regarded as a localized variant of the remarkable mask-like bilateral facial weakness that is seen in advanced parkinsonism.

---

* Based on a paper delivered at the Second British Academic Conference in Otolaryngology, 4 August 1967.

† Professor of Neurology, University of Newcastle upon Tyne.

There is one other feature of supranuclear palsy that deserves mention. For reasons that are obscure, disease in the temporal lobe sometimes produces facial paralysis closely simulating that caused by a lesion of the opposite facial nerve.

Nuclear and Infranuclear Lesions in the Pons

In the pons, facial weakness may be caused by damage to the nucleus of the nerve, or to its fibres as they pass through the pons in close relation to the sixth nerve nucleus to emerge from its lateral aspect. So there are really two anatomical varieties of intrapontine facial paralysis—nuclear and infranuclear. The widespread employment of vaccination against poliomyelitis may shortly render this disease obsolete, but there can be no doubt that typical lower motor neurone facial paralysis may be a sign, and indeed the only neurological sign, of an acute attack of paralytic poliomyelitis. We are not very likely to make a correct diagnosis of poliomyelitic facial paralysis except under epidemic conditions. On the other hand, such cases have occurred in every major outbreak. There is one clinical feature that might lead the observer to suspect a poliomyelitic aetiology. Poliomyelitic paralysis does not develop out of the blue in a perfectly fit patient. No matter how limited the paralytic phenomena there is likely to be a recent history of fever, headache, and neck stiffness that is lacking in the ordinary case of Bell's palsy. A clue in this connexion may also be furnished by the presence of fasciculation in the facial muscles. This may occur in any severe acute lower motor neurone lesion, but it tends to be more prominent and more constant where the nucleus itself is involved, and should lead one to suspect a nuclear rather than an infranuclear lesion.

If we seek an example of facial palsy of peripheral type arising within the pons from the emerging fibres rather than the nucleus of the seventh nerve, we need look no further than multiple sclerosis. It has often been remarked that facial paralysis is the only lower motor neurone lesion encountered in this puzzling disorder. It is not uncommon, and may either herald the onset of the disease or occur at any time during its course. Like most of the lesions of multiple sclerosis, facial palsy tends to recover. It can sometimes be distinguished from Bell's palsy by the absence of initial pain and by the fact that taste is not involved. This is, of course, because the lesion is due to a patch of inflammatory oedema or demyelination within the white matter of the brain stem, where the afferent fibres conveying taste in the accompanying *nervus intermedius* of Wrisberg have already left the entering facial nerve trunk on their way to the medullary *nucleus solitarius*. Unexpectedly, the facial paralysis that develops in the course of multiple sclerosis is infrequently associated with the concurrent involvement of the sixth nerve that might well be expected in view of the site of the lesion, or with the severe and prolonged vertigo that characterizes a more diffuse acute pontine lesion in multiple sclerosis.

The fact that flaccid palsy of the face may originate in the brain stem and not merely from the banal lesion of the facial nerve associated with the name of Sir Charles Bell emphasizes the need for neurological examination in facial paralysis to ensure that more generalized or serious disease of the nervous system is not overlooked.

Facial Nerve in the Cerebellopontine Angle

When the seventh nerve leaves the lateral surface of the pons it has a short intracranial course in the cerebellopontine angle before it enters the internal auditory canal, and in this situation it is susceptible to a number of pathological processes that often involve paralysis of other cranial nerves. The commonest cause of unilateral facial palsy originating in this part of the nerve is a space-occupying lesion, characteristically acoustic neurofibroma. Meningioma, chordoma, and aneurysm of the basilar artery are less frequent. Curiously, taste is often spared in lesions here. Paralysis arising at this site is often bilateral and may occur in any variety of chronic meningitis. The successes of chemotherapy have reduced the number of such cases, and today even syphilitic basal meningitis is a rarity. At the present time the commonest form of chronic meningitis is carcinomatosis, which often affects the facial among other cranial nerves.

Involvement of the nerve in its intracranial course before it enters the auditory canal is also the source of the bilateral facial weakness often encountered in the Guillain–Barré syndrome, a widespread lesion, certainly inflammatory and probably allergic, characterized by demyelination of proximal nerve roots with relative preservation of the axonal fibres themselves.

Lesions in the Internal Auditory and Facial Canals

Most cases of facial palsy originate in the bony canal that the nerve traverses between the internal auditory meatus and its emergence at the stylomastoid foramen. The most important cause within the internal auditory canal is acoustic neuroma, but whatever the lesion anatomical considerations predicate the frequent involvement of the eighth nerve. In severe cases paralysis of the greater superficial petrosal nerve, which leaves the geniculate ganglion, causes loss of both affective and reflex tear formation, and interruption of conduction in the chorda tympani leads to loss of taste in the anterior two-thirds of the tongue with diminished salivation. Where the patient escapes deafness, paralysis of the nerve to the stapedius occasionally leads to hyperacusis. Rarely a neurofibroma originates from the sheath of the facial nerve itself with similar results, and in exceptional cases changes seen on an *x*-ray film may indicate the origin of a similar syndrome in an intratemporal dermoid cyst.

The geniculate ganglion owes its picturesque reputation in clinical neurology to the historic contribution of Ramsay Hunt in 1907, who described the condition known as geniculate herpes—a syndrome consisting of acute facial paralysis and a rash in or behind the ear, with or without deafness and vertigo. That such a syndrome is occasionally encountered cannot be denied, but that it arises from changes in the geniculate ganglion itself is open to question. The frequent relation of the syndrome to herpes zoster is indubitable, and has been confirmed by serological tests. However, the situation of the rash is inconstant, and it may be present on the tongue, in the trigeminal distribution, or even in the upper cervical region. Zoster is a general infection by a neurotropic virus, and the fact that every level of the sensory system is pathologically affected probably accounts for the extreme intractability of post-herpetic neuralgia. Facial palsy is one of the uncommon motor complications of zoster which are probably due to a spread of virus from sensory to motor neurones, producing a lesion comparable with that of poliomyelitis, rather than to the inflammatory swelling of the nerve trunk in the facial canal so often suggested as its basis. If the paralysis is indeed due to invasion of the motor nerve cell by virus, peripheral decompression of the nerve is unlikely to help.

There are some conditions other than Bell's palsy, chronic otitis, cholesteatoma, and mastoidectomy that may affect the facial nerve in its bony canal. Among the most important is head injury, and this presents some points of special interest. The first is that post-traumatic facial paralysis nearly always recovers spontaneously. I know that some surgeons operate on these cases as a routine; their example is not followed by English neurosurgeons. Indeed, my own experience and that of the Newcastle School of Neurosurgery, as well as that of such authors as Ritchie Russell (1960) and Brodie Hughes (1964), indicate such a good outlook as to permit the argument that leaving the condition alone produces results that are actually better than, and not merely as good as, those of operation. The small proportion of cases where there is no recovery arise where the facial nerve has been actually torn across in a severe fracture of the middle fossa. With this exception post-traumatic facial palsy nearly always shows good recovery, whether it is sustained at the time of injury, develops within two or three days, or—as occasionally happens—begins two or three weeks after the accident.

Facial paralysis complicating head injury is, of course, commonest where there has been bleeding or a discharge of spinal fluid from the ear, and there is often coincident deafness from middle-ear damage. Taste is frequently involved.

There are some rarer but interesting causes of paralysis of the facial nerve arising in this part of its course. It may be compressed by leukaemic deposits. It is a well-known occasional manifestation of severe hypertension, occurring acutely, for example, in the child with acute glomerulonephritis or in the pregnant woman with toxaemia, probably due to haemorrhage into the canal. Sarcoidosis is another occasional cause in a young patient, with a negative Mantoux reaction and often with uveoparotid fever or systemic evidence of sarcoidosis. In most such instances the paralysis is bilateral and is due to granulomatous involvement of the nerve either within or just outside the auditory canal. Again, although decompression has been advised, spontaneous recovery is usual.

Before we consider Bell's palsy, some lesions of the facial nerve after it has left the stylomastoid foramen deserve brief mention. The trauma of a stab wound or of parotid gland surgery are occasional causes. Prolonged excessive opening of the mouth during dental procedures is occasionally responsible. However, probably the commonest mechanical cause is forceps delivery or difficult labour, and in these instances the complete or partial flaccid weakness of the face that ensues usually recovers within a week of the baby's birth. Parotid tumours themselves often cause facial paralysis, and this tends to be subacute and to involve the branches of the nerve unevenly and progressively. Leprosy produces a rather similar neurological lesion, but it is worth noting that this is the only cause of bilateral facial paralysis in which the upper face is more often affected than the lower.

Bell's Palsy

Bell's palsy can often be distinguished from other forms of facial paralysis by the local pain that precedes it, usually with tenderness on pressure over the stylomastoid foramen in front of the ear, and also by the acuteness with which the paralysis develops. Often this is already virtually complete when the patient becomes aware of its existence, and it is exceptional for its development to occupy more than a few hours. Food sticks uncomfortably in the cheek because of buccinator paralysis, inadequate closure causes the eye to water, and in the elderly all the muscles of the affected side of the face sag. Slight deafness and tinnitus may occur but are always transient. The ear-drum may be pink and congested. Loss of taste occurs in about 10% of cases: for the most part these are more than averagely severe, and the symptom is of unfavourable prognostic significance. Though the sensory fibres of the facial nerve are probably involved in severe cases, the loss of sensation behind the ear that might be anticipated is never encountered, almost certainly because of overlap.

The history of an acute and non-progressive lesion is characteristic, and though this may also be a feature of facial paralysis in multiple sclerosis (unilaterally) and the Guillain–Barré syndrome (bilaterally) pain is absent in both these instances.

Differential diagnosis is implicit in the accounts that have already been given of other kinds of facial paralysis. Under outpatient conditions middle-ear disease, significant deafness, hypertension, involvement of other cranial nerves, and evidence of organic disease of the nervous system must all be carefully excluded. If these precautions are taken in cases where the history is typical, the chances of serious diagnostic error are probably less than in most neurological disorders. The serological exclusion of syphilis is traditional, but I have never found it contributory, nor have I ever found facial paralysis to be a harbinger of diabetes. It is more important to bear in mind that *progressive* paralysis virtually excludes the banal diagnosis.

Recurrent Bell's palsy rightly arouses suspicion, but the condition is not very uncommon, especially in younger patients, in whom the nerve may be affected on both sides at different times. The occasional familial incidence of this syndrome suggests the incrimination of some minor anatomical anomaly.

Prognosis and Sequelae

Arguments about prognosis are confused by a frequent failure to distinguish complete from functionally adequate recovery. It is certainly true that nine out of 10 patients with Bell's palsy do well enough from the functional and cosmetic points of view to make routine surgery unjustifiable. This is not to say that they recover completely. In some, either inappropriate associated movement or a shadow of residual weakness is detectable on careful examination, but amounts to nothing in the way of actual disablement. If any voluntary movement whatever is present five days after the onset, functional recovery will be nearly perfect, even where some evidence of denervation and reinnervation remains.

The fact remains that in about 10% of all cases there is persisting paralysis, often with troublesome permanent sequelae. Nearly all these patients have shown a complete loss of nerve conduction within a few days of onset, and in most of them taste has been noticeably impaired. The sequelae include ectropion, facial contracture on the affected side, inappropriate contraction of the affected side of the face on contraction of the normal side, and occasionally clonic facial spasm or crocodile tears, both of which usually begin some months after onset. Numerous explanations have been offered to account for crocodile tears, but the likeliest is misdirection to the lacrimal of regenerating fibres intended for the salivary glands. The failure of co-ordinated facial expression evident in closure of the eyelid on opening the mouth after recovery from Bell's palsy is also probably due to misdirection of regenerating axones.

Early Recognition of Unfavourable Cases

The real issues concern, firstly, the early recognition of this small proportion of unfavourable cases, and, secondly, a critical examination of the evidence that any of the surgical measures advised have been convincingly shown to improve the outcome.

In about 50% of all cases conduction time in the peripheral part of the facial nerve is never impaired, electromyographic fibrillation never appears, and recovery will be complete. In rather more than 30% a transient slowing of conduction indicating partial denervation occurs, but functional recovery is complete. In a minority, however, the nerve becomes unresponsive to stimulation within a few days of the onset and denervation is complete. It is this group that furnishes the residue of cases with persisting paralysis and the complications already described. Electromyographic evidence of fibrillation may be delayed for two to three weeks, and is therefore of little value in any early decision about surgical decompression. Since perfect or at any rate adequate recovery is almost certain unless complete denervation is present at the end of the first week, conduction velocity should be measured at this stage in patients who show no sign of recovery. The high correlation of denervation with loss of taste confirms the prognostic value of this symptom.

Dr. Taverner has been a pioneer in this field (Taverner, 1959 ; Langworth and Taverner, 1963). It is clear that the combination of simple clinical and electrophysiological data facilitates prognosis and the formulation of criteria on which to base controlled therapeutic trials.

Unfortunately the proponents of surgical decompression can quote no such controlled observations, and base their practice on the uncertain grounds of theoretical justification and clinical impression. To the best of my knowledge the nearest published approach to a controlled trial of this form of treatment is found in some fragmentary but suggestive observations made at the Royal Free Hospital in London (Groves, 1965). Groves selected 10 cases of Bell's palsy in which nerve conduction had been lost, thereby fulfilling Dr. Taverner's criteria for complete denervation, and decompressed the nerve in five of these patients shortly after onset. These five did worse than a similar group who declined operation (Groves, 1967). The figures are small, but the value of decompression would need to be firmly established on the basis of similarly strict criteria.

Where is the Lesion ?

The site of the lesion in Bell's palsy has been sought by neurophysiological methods and by surgical exploration. Jepsen (1965) and Zilstorff-Pedersen (1965) used similar techniques, comprising quantitative studies of taste, elicitation of the stapedius reflex, and measurement of lacrimation. Their results were identical. Except in a very small minority of cases the lesion was localized below the geniculate ganglion, and in about half below the origin of the chorda tympani. Of those above the chorda tympani about half are above the nerve to the stapedius and half below. In other words, the findings of applied neurophysiology support those of the many surgeons who have decompressed the nerve, and confirm Sir William Gowers's clinical pronouncement that the lesion involves especially the part of the nerve trunk that lies within the lower part of the facial canal.

Recalling similarly graphic descriptions of the operative appearances of the sciatic nerve in syndromes which we now know to have had their origin at a much higher level from disc prolapse, the physician may be pardoned an unworthy suspicion that the surgeon who describes the swollen and congested facial nerve observed at operation for decompression is less likely to be familiar with the appearance of the entirely normal nerve under similar circumstances. He may even have some reservations about statements that the histopathological findings encountered in the very rare cases that have come to necropsy favour an ischaemic rather than an inflammatory pathogenesis, or that swelling of the nerve within its sheath is more significant than compression by the bony canal. However, he will be more impressed by experimental observations that transient facial paralysis can be produced in the experimental animal by injection of saline into the nerve within but not outside the facial canal (Jain and Sharma, 1964). This experiment may well be relevant to both the pathogenesis and the prognosis of Bell's palsy. It would fit well with the varying severity of the lesion and with the concept of an initial simple conduction block, below which the nerve will remain healthy, with a normal conduction velocity, unless compression is sufficiently severe and prolonged to cause death of the axone below. Such a view of the lesion is compatible with everything we know about the pathogenesis of Bell's palsy, but contributes nothing to aetiological knowledge, a situation with which we are all too familiar in neurology.

Aetiology

Both sides of the face are equally affected, the disease is somewhat more frequent in older age groups, it manifests no convincing seasonal incidence, and it does not occur in epidemic form. On the other hand, we know that acute facial palsy occurs as an occasional complication of certain virus infections, as well as quite often in the course of the Guillain–Barré syndrome. We remain uncertain whether the pathology in these cases is similar to that of Bell's palsy, and in the case of the Guillain–Barré syndrome the initial lesion is in fact likely to be both demyelinative and more proximal, in keeping with the general pathology of the condition.

It is truly remarkable that we really have no idea regarding the cause of this simple and ubiquitous condition, and are uncertain whether it is a result of ischaemia produced by exposure to cold, due to virus infection, or a variant of the allergic neuritis that can be produced by antigen-antibody reactions both in man and in the experimental animal. Bell's palsy takes its place among such mysterious conditions as neuralgic amyotrophy, retrobulbar neuritis, and paralysis of the long as well as the short nerve of the distinguished anatomist who gave it his name (Bell, 1829).

Treatment

Only 10% of all patients with Bell's palsy are ultimately dissatisfied with the outcome. Recovery may not be electrophysiologically or even clinically complete, but it is functionally and cosmetically adequate. The value of radical treatment can be assessed only by its effect on this critical 10% of patients.

With regard to general management, the elderly patient may need to be reassured that the condition is not a stroke. Neither massage nor galvanism has any proved value in the treatment of this condition, and merely fill the physiotherapy department with people who should be at work. There is no earthly reason why cervical sympathetic blockade should be of value in Bell's palsy and no evidence that it is. Few of my patients have found the wearing of a wire splint or a piece of strapping on the face worth the trouble involved, but some with persistent paralysis have been helped by plastic surgery.

I have never referred a patient for surgical decompression, and in view of recent therapeutic developments I am unlikely to do so in the future. What is really important, where the paralysis is severe enough to prevent reflex blinking, is to protect the eye. If complete disappearance of reflex blinking leaves a good deal of cornea permanently exposed a patch should be worn over the eye and bland drops used several times daily. The reflex usually recovers fairly quickly, but if not the help of an ophthalmologist should be sought in management.

The validation of treatment with A.C.T.H. represents the most important therapeutic advance in the history of Bell's palsy. Dr. Taverner's careful observations (Taverner *et al.*, 1966) confirm my own less organized experience that really early treatment is highly successful. Recent controlled observations in Manchester have confirmed a similar though rather less dramatic efficacy of the same form of treatment in retrobulbar neuritis (Rawson *et al.*, 1966). With regard to Bell's palsy, a form of treatment that produces satisfactory results in 76 out of 77 cases leaves little room for improvement. The earlier treatment begins the better, and even on present evidence both efficiency and economy might best be served by side-stepping special investigations and regarding the condition as one to be treated at once by the general practitioner with a short course of A.C.T.H. Direct evidence of the effectiveness of prednisone in the treatment of this condition is lacking, but it is possible that in really adequate dosage it would prove as effective as the less convenient pituitary hormone: a careful trial of early treatment with the oral preparation would be a very suitable project for the Research Committee of the College of General Practitioners.

Observations on Interpretation of Blood Alcohol Levels Derived from Analysis of Urine

Brit. med. J., 1967, **3**, 819–823

For many years it has been customary to derive blood alcohol concentrations from the analysis of urine, and despite the fact that the accuracy of such derivations has often been questioned British courts have been content to accept them as evidence in prosecutions for drunken driving, presumably on the grounds that such evidence was merely confirmatory and not vital. However, with the impending change in the law which will make it an offence to drive with more than a stated amount of alcohol in the blood, the reliability of the method of determining blood alcohol concentrations assumes much greater significance, particularly as the use of urine analysis has not been excluded (Ministry of Transport, 1965).

In the interpretation of blood levels derived from urine analysis two problems arise. The first concerns the accuracy of the analytical method used to measure the alcohol concentration in urine, and the second is related to the choice of the conversion factor for the derivation of blood level. In the case of urine analysis the accuracy of the Nickolls modification of the Cavett technique is well established, but the method is tedious, time-consuming, and critically dependent on the technical skill of the operator. Gas chromatography is free from these disadvantages (Chandela and Janák, 1960), and it is claimed that when used in combination with an internal standard and an integrator the alcohol content of a minute sample of either blood or urine can be measured accurately within five minutes (Curry, Walker, and Simpson, 1966). One purpose of the investigation to be described was to determine the accuracy of the gas chromatographic method.

In the case of the conversion factor no unanimity of opinion exists about the correct choice, and it was the second purpose of the investigation to examine the validity of the conversion factor of 1.33 recommended in the Report of a Special Committee of the British Medical Association (1965).

Material and Methods

During the Christmas period of 1966 and the succeeding weeks one of us (D. V. F.) in his capacity as police surgeon obtained two specimens of urine at known time intervals and one of venous blood and sometimes one of capillary blood from 35 motorists suspected of driving under the influence of drink. The times at which the samples were obtained were noted and the samples themselves were divided into three equal parts for distribution to the suspect, the police laboratory, and this department. Anonymity was preserved by the designation of a reference number. Initially the samples were analysed both by the Nickolls (1960) modification of the Cavett technique and by the gas chromatographic technique described in detail by Curry *et al.* (1966) but modified to use a Poropak Q porous polymer bead column instead of a polyethylene glycol 400 column. The Poropak column offers the advantage of a much lower column bleed and elutes the water peak first after 30 seconds followed by ethanol at 1.5 minutes and n-propanol at 3.5 minutes. With polyethylene glycol, unless the column is carefully conditioned with water before use, a tailing water peak is produced which prolongs the analysis. Latterly the samples were analysed by the gas chromatographic method alone.

For chromatographic analysis the blood or urine sample was diluted with ten times its volume of an aqueous solution containing 24 mg. of propranol per 100 ml. to act as an internal standard. One microlitre (μl.) of this diluted sample was injected into the Poropak Q chromatographic column maintained at 170° C. The resultant peaks were detected by a flame ionization detector and the output signals fed into a digital integrator. Whenever possible the analyses were carried out in triplicate.

The accuracies of both the Nickolls and the gas chromatographic methods were tested by analysing samples of pure water and normal blood to which known quantities of alcohol had been added to achieve a range between 52 and 242 mg./100 ml. The purity of the absolute alcohol used in the preparation of standards was certified by the Laboratory of the Government Chemist using a refractive index method, as were the dilute solutions of standards. The solutions themselves were prepared by weight by means of an accurate analytical balance to achieve an alcohol content in distilled water which was between 30 and 32 mg./ml. In the preparation of the blood samples the alcohol solution was added by weight to a flask containing a known weight of blood equivalent to not less than 50 ml. The blood itself was magnetically stirred during and after the transfer for five minutes.

When the values for urine and the corresponding venous blood had been obtained it became obvious that additional information on urine: blood ratios would be an advantage. The co-operation of the forensic laboratories was sought and Dr Morgan, of the Department of Industrial and Forensic Sciences in Belfast, supplied values additional to those already published (Morgan, 1965), which allowed a more extensive statistical analysis based on a computer programme specifically designed for the purpose. The programme was used to obtain mean urine and blood values together with their standard deviations, to calculate individual and mean urine:blood ratios, and to determine their distribution. In the case of our own observations a corrected urine:blood ratio was also derived which took into account the time difference between the collection of the venous blood specimens and the corresponding second urine specimens.

* Research Department of Anaesthetics, Royal College of Surgeons of England, London W.C.2.

Because of the suggestion that capillary blood could provide a satisfactory answer to the problem of blood sampling, both venous blood and capillary blood samples were collected whenever possible. The venous samples were obtained in 20-ml. Steriseal syringes from a superficial vein on the forearm after preparing the skin with cetrimide *B.P.* solution. After collection the samples were decanted into the standard 5-ml. fluoride-oxalate bottles available in the police station. The capillary samples were obtained from a stab puncture on the ball of the thumb and collected in capillary tubes or in plastic pots.

Four types of glass capillary tubes were used. The first was the standard straight capillary tube (type D.551) supplied for blood-gas estimations by Radiometer Limited, Copenhagen. These tubes are heparinized, have a capacity of 60–80 µl., and are fitted with plastic caps and a magnetic armature to facilitate mixing. The second type was also straight but was larger, with a capacity of 150 µl., and was coated with fluoride-oxalate. These tubes were manufactured by Harshaw Chemicals Limited, of Daventry, for the East Midland Forensic Science Laboratory. The third type was U-shaped, had a capacity of 140 µl., and was supplied to the Northern Forensic Science Laboratory by MacFarlane Robson Limited, Blaydon, Newcastle upon Tyne. Fluoride-oxalate was used to prevent clotting in the U tube and also in the fourth type, which was S-shaped with a capacity of 150 µl. The S-shaped tubes were made by Morbank Limited, of Pontypridd, for the Home Office Central Research Establishment. Both the U-shaped and the S-shaped tubes were originally designed to facilitate weighing on a torsion balance in relation to the estimation of blood alcohol content by another technique. The polypropylene plastic pots, which were heparinized, had a capacity of 300 µl., and were supplied to the North-Western Forensic Science Laboratory by Tinker Grayson Limited, Huddersfield.

Early in the study certain discrepancies were noticed in the determinations of the alcohol content of capillary blood. Because of these discrepancies the co-operation of the Home Office laboratories was again sought, and blood samples collected in capillary tubes and plastic pots from volunteers in this department were distributed to a number of centres for analysis.

On five occasions, in addition to measuring the alcohol concentration in whole blood, that in plasma and in red blood cells was also determined. For this purpose 10–15 ml. of the blood sample was placed in a glass test-tube sealed with a ground-glass stopper and centrifuged at 2,300 r.p.m. for 20 minutes at room temperature in a Griffin-Christ centrifuge (type UJ 3). At the end of this period the separated plasma was pipetted into a second tube, which was then sealed until analysed by gas chromatography. Because the packed cells tended to block the needle of the microsyringe when inserted into the heated inlet tube of the gas chromatograph the alcohol content of the red blood cells was measured by the Nickolls method. Two-millilitre aliquots of undiluted packed cells were used for this analysis; this had the added advantage of eliminating the possible difficulties of handling minute quantities of red blood cells. The haematocrit value for each blood sample was determined and this together with a correction factor for trapped plasma (Chaplin and Mollison, 1952) was used to calculate the alcohol concentration in whole blood.

Results

Accuracy of Gas Chromatography

In preliminary studies known amounts of ethanol were added to 15 blood samples to achieve concentrations in the range from 52 to 242 mg./100 ml. On analysis 98% recovery was achieved on average with the Nickolls method, with a correlation coefficient of 0.99 between duplicate samples. The gas chromatograph gave equally satisfactory results; 99% of the added ethanol was recovered and the correlation coefficient for duplicate samples was again 0.99.

Known amounts of ethanol were added to water to achieve concentrations between 76 and 197 mg./100 ml. and 13 separate samples were analysed in duplicate by the two methods. With the Nickolls method 100% of the added alcohol was recovered and the correlation coefficient between duplicate samples was 0.99. Gas chromatography was slightly less efficient; the percentage recovery was 97 and the correlation coefficient 0.97.

Despite the apparently satisfactory recovery achieved with gas chromatography from blood, the Nickolls method continued to be used during the initial stages of the study of blood and urine obtained from suspects. The first 12 samples were analysed in duplicate by the Nickolls method and in triplicate by gas chromatography. Comparison of the results obtained by the two methods gave a correlation coefficient of 0.99, and this provided the justification for continuing the study by gas chromatography alone.

Urine : blood Ratios

The analyses of one blood and two urine samples from 35 suspects gave 70 paired results, and the details are set out in Table I. The mean alcohol concentration of 35 first urine samples was 262±54 mg./100 ml. The corresponding mean

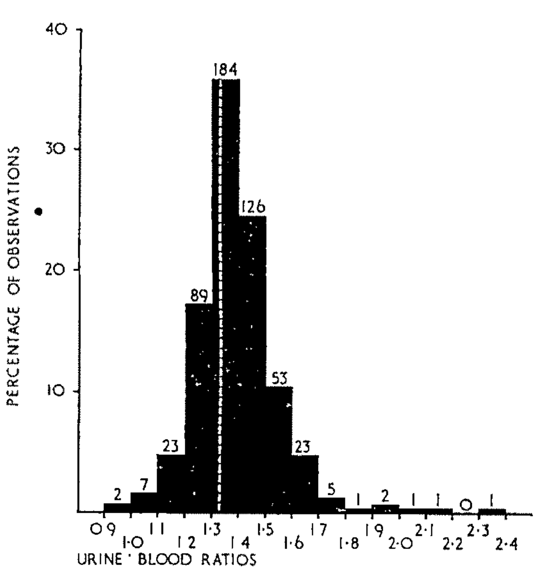
T_2 Time interval between collection of blood sample and second urine sample. A negative value signifies that the urine sample was collected before the blood sample.

for the second urine samples was 258±71 mg./100 ml., and the mean venous blood value was 183±55 mg./100 ml. When both first and second urine values are used these figures give an overall urine:blood ratio of 1.42:1. Of the 35 second urine samples analysed 25 were collected after the peak alcohol concentration in urine had been reached. When these were related to the corresponding blood values a mean urine:blood ratio of 1.44:1 was obtained. However, individual ratios in this second group varied from 1.10 to 2.44:1, and the range was even greater in the first group, from 0.82 to 2.59.

An attempt at back-calculation was made. For this purpose the alcohol clearance from the blood was derived from values obtained in a previous study (Payne, Hill, and King, 1966). Results from 16 volunteers were analysed, and it was found that the rate of clearance varied between 10 and 38 mg./100 ml./hour, with a mean value of 24 mg. No correlation with the weight of the subject could be obtained. The mean value was used to derive a corrected urine:blood ratio of 1.48.

From the 518 paired urine and blood results made available from Belfast the mean urine:blood ratio was 1.38. The distribution of these ratios is set out in the Chart. Just over 35% of these results fall into the ratio range of 1.30–1.39:1. The range of urine values was from 43 to 481 mg./100 ml., and the urine:blood ratios extended from 0.92:1 to 2.32:1.



Percentage distribution of the urine:blood ratios derived from Belfast data. The figures at each step denote the actual number of ratios determined. The dotted line indicates the urine to blood ratio of 1.33.

Capillary Blood Analysis

In most instances the alcohol content of the capillary blood was substantially below that of the corresponding venous blood. In the case of the straight tubes 10 separate samples contained, on average, 61% of the alcohol content found in the corresponding venous blood. When the U tubes were used 10 tubes contained an average of 79% of the alcohol content of the corresponding venous blood. Of 10 samples collected in S-shaped tubes six contained, on average, only 53% of the alcohol content of the corresponding venous sample; the remaining four tubes had an alcohol content 7% higher than the venous blood. The capillary blood collected in the 11 plastic pots had a higher average alcohol concentration than that of the tubes but still contained only 90% of that found in the corresponding venous blood.

Of the limited number of capillary tubes and polypropylene pots distributed to other departments, only the samples stored in the pots gave good agreement on analyses. There were wide discrepancies in the results obtained from the capillary tubes.

Plasma : Red Blood Cell Ratios

The distribution of alcohol in the plasma and packed cells of whole blood was studied in five venous samples, and the relevant data are set out in Table II. The calculated alcohol content of whole blood in column 5, derived by measuring the packed cell volume and the alcohol content of both plasma and red blood cells, largely confirmed the accuracy of the methods used. A mean plasma:red blood cell ratio of 1.43:1 was obtained and a somewhat lower ratio of 1.15:1 expressed the relation between plasma and whole blood.

Discussion

The conclusion by Curry *et al.* (1966) that when gas chromatography is combined with an internal standard and an integrator the alcohol content of small samples of body fluid can be measured accurately within five minutes has been substantiated.

The fact that the alcohol content of urine can be measured accurately does not necessarily mean that an exact determination of the amount of alcohol present in blood can be derived from urine analysis. The considerable difference of opinion on the correct conversion factor to be used implies a degree of uncertainty that is amply justified by experiment. On the basis of more than 7,000 analyses of urine and the corresponding blood samples Froentjes (1963) calculated the ratio of urine alcohol to blood alcohol as 1.52:1. He emphasized, however, that if this conversion factor was applied a 50% chance existed that the actual blood alcohol concentration would be lower than the calculated value, and for this reason in practice he advocated the use of a conversion factor of 2:1. Notwithstanding Froentjes's views the special committee of the British Medical Association set up to consider the problem of the drinking driver came to the conclusion that once the peak concentration in the urine had been passed a urine to blood ratio of 1.32:1 could be adopted. Using this ratio, Payne *et al.* (1966) demonstrated good agreement between urine and blood analyses when studying the uptake, distribution, and elimination of alcohol in a group of healthy volunteers. But these results were obtained under well-controlled conditions in the laboratory, and the present work, confirming that of Stevens, Mason, and Bowden (1966), shows that it would be invalid to use this factor in the less rigidly controlled environment of a busy police station.

That this is so is apparent from the data presented. Of the 518 paired urine and blood samples analysed in Belfast an overall urine:blood ratio of 1.38:1 was obtained, but only 35% fell into the range from 1.30 to 1.39:1, and the remainder extended from 0.92 to 2.32:1.

Further evidence of the variation in urine:blood ratios was obtained from the analyses of the blood and urine samples presented in Table I. Of the 35 second urine samples obtained from detained motorists, 25 had an alcohol concentration equal to or lower than the first, and were therefore to be regarded as having been collected after the peak concentration in urine had been passed. The significance of this has been discussed by Payne *et al.* (1966). These values gave a mean ratio of

1.44:1, somewhat higher than the 1.32 recommended by the special committee of the B.M.A. In only one of these 25 suspects was a precise urine: blood ratio of 1.32:1 obtained, and the range was from 1.10 to 2.44, substantially greater than that of 1.2:1 to 1.4:1 quoted in the B.M.A. report. The overall mean ratio for the second urine samples was 1.41. Furthermore, as has been shown previously (Payne *et al.*, 1966), it is apparent from the data in Table I that the urine: blood ratio is not even constant for one individual but varies with time.

The argument is of considerable practical importance; for example, if the urine analysis of Subject No. 10 in Table I had given a value of between 110 and 150 mg./100 ml. the use of the conversion factor of 1.32 would yield a blood alcohol concentration of between 82 and 112 mg./100 ml., a level which almost certainly would lead to his conviction under the new Act. But in this particular individual the urine: blood ratio was measured and found to be 1.84:1, which under the circumstances described yields an actual blood concentration between 60 and 80 mg./100 ml., a level below the maximum envisaged as compatible with safe driving in the White Paper on Road Safety Legislation (Ministry of Transport, 1965). In the case of Subject No. 25, whose urine: blood ratio was 2.44:1, the discrepancies would have been greater. Thus the suggestion by the Special Committee of the B.M.A. that any injustice to individuals was extremely unlikely when a urine to blood ratio of 1.33:1 has been used will certainly cease to be true if present proposals become law. (The B.M.A. report used the factors 1.32 and 1.33 at various times.) Indeed there is every likelihood that the uncritical acceptance of a urine to blood ratio of 1.33:1 will lead to miscarriages of justice when it becomes an offence to drive or to be in charge of a motor vehicle with more than a stipulated amount of alcohol in the blood.

As might have been expected from the variation in the rate of removal of alcohol from blood the attempt at back calculation not only failed to bring the urine to blood ratio closer to 1.33:1, it also confirmed the difficulty of interpolating accurately a blood alcohol level to an earlier point in time.

The failure to obtain definitive results from urine analysis focused attention once again on blood. The lack of enthusiasm among doctors for venepuncture combined with the convenience and accuracy of gas chromatography suggested that capillary blood analysis might prove an acceptable compromise. Unfortunately, most capillary blood samples were found on analysis to contain substantially lower alcohol concentrations than the corresponding venous samples. Two possibilities existed: either the alcohol concentration in capillary blood was in fact lower than in the corresponding venous blood, or some of the alcohol content was lost after the blood was shed. Since Harger (1963) and his colleagues have shown that the alcohol content of capillary blood is not lower than that of venous blood, it must be accepted that loss has occurred.

The most likely time for such loss is during collection, especially if the flow of blood is too slow to allow rapid filling of the capillary tube; ethyl alcohol is sufficiently volatile to be lost fairly rapidly from exposed blood at body temperature. Another possible source of loss is from the capillary tube, either by a leak past the plastic seal or by adsorption by the seal itself; plastic materials have recently been shown to interfere with several blood constituents (Whitehead, 1967, personal communication). The capillary tubes themselves were glass, so that loss through the walls was unlikely. When polypropylene pots were used to collect capillary blood the alcohol content of the samples was closer to the venous level than was that in the capillary tubes, but some loss was apparent and it is possible that adsorption on the walls or even diffusion through them had taken place. However, the fact that good agreement was obtained when separate aliquots of the same samples were analysed by different laboratories suggests that the loss probably occurs during sampling rather than during storage in the pot.

During the investigation of this loss it was observed that the blood in some S-shaped and U-shaped capillary tubes had a substantially higher alcohol content than the corresponding venous blood. These high contents were associated with separation of plasma from red cells within the tube, with problems of mixing and with subsequent difficulties in obtaining good agreement on duplicate analyses; therefore the possibility that alcohol was distributed unevenly between plasma and red blood cells was considered. Definitive information on this aspect is limited; however, Grüner (1957) has shown that alcohol is distributed in human plasma and in whole blood in a ratio of 1.15:1, and is dependent on the distribution of water as suggested by the work of Polonovski, Lindenberg, and Rabussier (1951) on dogs. The evidence reported here confirms and amplifies these observations.

The fact that human plasma contains about 40% more alcohol than an equal volume of red blood cells would explain the high alcohol content in some capillary tubes, but it also raises new problems. In particular, it implies that certain accepted standards such as the urine to blood ratio and the blood to breath ratio cannot be constant, but must be related to the haematocrit. It also implies that the plasma alcohol concentration might be a more useful determination for future experimental work if it is assumed that tissue levels are in equilibrium with the plasma. It would certainly help to explain the difficulties that have been encountered in seeking an answer to the apparent discrepancies in the blood: breath ratio.

Conclusions

From the data presented certain conclusions can be drawn.

Firstly, the fact that the urine to blood ratio is not constant at 1.33:1 means that an accurate estimation of a blood alcohol level cannot be derived from the analysis of urine with any degree of certainty when a urine to blood ratio of 1.33:1 is used.

Secondly, the difficulties encountered in the analysis of capillary blood suggest that the determination of blood alcohol levels should be carried out on venous blood until these difficulties have been overcome. The possibility that unsatisfactory handling techniques are involved emphasizes the need to establish a standard protocol for the withdrawal and handling of blood for the determination of alcohol levels.

Thirdly, the demonstration that human plasma contains about 40% more alcohol than an equal volume of red blood cells strengthens the argument for such a protocol. It also implies that the alcohol concentration might be better measured in plasma rather than in blood in experimental studies.

Summary

The fact that gas chromatography when combined with an internal standard and an integrator will measure the alcohol content in minute samples of body fluids rapidly and accurately has been confirmed.

The analysis of blood and urine samples from 35 motorists suspected of driving while under the influence of drink gave a mean urine to blood ratio of 1.44:1, substantially higher than the recommended conversion factor of 1.33:1. Moreover the range of values found—from 1.10 to 2.44:1—suggests that the uncritical acceptance of this urine to blood ratio of 1.33:1 will lead to miscarriages of justice when it becomes an offence to drive or to be in charge of a motor vehicle with more than a stipulated amount of alcohol in the blood.

The failure to obtain good agreement between capillary blood samples and the corresponding venous samples when analysed for alcohol indicates that it would be unwise to depend on capillary blood analysis for accurate results at the present moment. Probably the discrepancies are due to sample-

handling difficulties, which may be overcome with more experience.

The analysis of five samples of human blood showed that when alcohol is present the plasma contains over 40% more than whole blood (plasma to R.B.C. ratio, 1.43 : 1 ; plasma to whole blood ratio, 1.15 : 1). Thus the alcohol content of a given blood sample will be critically dependent on the separation or otherwise of plasma from red blood cells during handling.

We are indebted to the directors of the Metropolitan Police Laboratory ; the Home Office Central Research Establishment ; the North-Western (Preston), the Northern (Newcastle), and the East Midland (Nottingham) Forensic Science Laboratories ; and the Department of Industrial and Forensic Science (Belfast) for their cooperation. We are also grateful to Professor F. E. Camps and Dr. E. G. Davies for advice and criticism.

Addendum

Since this paper was written the Road Safety Act 1967 has been published. In section 7 subsection (4) it is stated that "For the purposes of this Part of this Act 107 milligrammes of alcohol in 100 millilitres of urine shall be treated as equivalent to 80 milligrammes of alcohol in 100 millilitres of blood."

What in effect this means is that it becomes an offence to drive or to be in charge of a motor vehicle when the alcohol content of the urine is 108 mg./100 ml. or more. But of the 35 suspects studied in our series no fewer than 19 would have had less than 80 mg. of alcohol per 100 ml. in blood when the equivalent urine sample contained 108 mg./100 ml.; indeed subject No. 25, whose urine to blood ratio was 2.44 : 1, would have a blood level of only 44.3 mg. of alcohol per 100 ml. at this urine level.

Thus the warning given in our paper that the uncritical acceptance of a urine to blood ratio of 1.33 : 1 will lead to miscarriages of justice when it becomes an offence to drive or to be in charge of a motor vehicle with more than a stipulated amount of alcohol in the blood is entirely justified. In the interests of justice therefore suspected drivers would be well advised to insist on a blood specimen being taken if asked to provide a sample of urine for examination.

Splenectomy in "Big Spleen Disease"

Idiopathic or cryptogenic tropical splenomegaly is sometimes treated empirically by splenectomy. Moreover, in areas where this condition is commonly encountered medical facilities are usually not available for the full investigation of such cases before or after splenectomy. Recently, a group of patients suffering from idiopathic tropical splenomegaly were studied in detail in the Mulago Hospital, Kampala, Uganda. All known causes of tropical splenomegaly were excluded in these patients, who on liver biopsy showed varying degrees of lymphocytic infiltration of the liver sinusoids and Kupffer-cell hyperplasia. In addition they all had high fluorescent antibody titres for malaria. This association is known locally as "big spleen disease" (Hamilton *et al.*, 1966) and is referred to by that title in this paper. Williams *et al.* (1966) showed in haemodynamic studies that these patients suffered from considerable portal hypertension, apparently due to increased spleen blood flow. Richmond *et al.* (1967), reporting the haematological findings on the same group of patients, found that they all had anaemia, sometimes of severe degree, and this appeared to be due to sequestration of a large proportion of the red cell mass in the spleen, expansion of the plasma volume, and reduction of the red cell life-span. Seven of the 15 patients were treated by splenectomy in June–July 1965, the indications for splenectomy being either incapacitating abdominal pain or discomfort or the finding of pronounced hypervolaemia with anaemia. Follow-up studies on these seven patients two months after splenectomy showed satisfactory improvement in the haemoglobin level in six of them and correction of the red cell survival time in the four in whom this was measured.

This paper describes follow-up studies on five of the splenectomized patients 15 months after the operation.

Patients and Methods

Six of the seven patients splenectomized in June–July 1965 were traced to their homes in October 1966 by one of us (V. L.) ; one patient, who was in good health, could not be traced. Five patients were studied in detail.

All were males aged 20–55 years. Full clinical examination, routine haematological tests (Dacie and Lewis, 1963), standard liver-function tests, and brucella and salmonella serum agglu-

tination reactions were carried out. Each patient had a liver biopsy by the Menghini technique. The serum fluorescent antibody titre for malaria was measured, ***Plasmodium falciparum*** being used as antigen (Voller, 1964). Plasma volumes were estimated by ^{131}I-labelled human albumin ; the test sample being taken 20 minutes after the injection of albumin.

Results

Subjectively all the patients felt much better after the operation and were particularly relieved of their constant abdominal discomfort. Four patients had put on weight and all had been able to work again. No patient had had a haematemesis or melaena. Immediately after the operation all had been started on antimalarial drugs prophylactically, these being continued for six to eight months ; after this interval they all defaulted from further attendance. None of them had taken antimalarial drugs for at least six months previous to this study. They all complained of occasional attacks of fever, but none of them described having had a classical attack of malaria.

On examination they looked well, liver size was not significantly different from that before operation, and there were no other abnormalities.

Haematological Changes.—The haematological findings are given in the Table. There was a marked rise in haemoglobin level and haematocrit values in all cases. Except for one patient (Case 1) who had a reticulocytosis of 6%, the postoperative reticulocyte counts were not significantly different from those before the operation. In all cases the plasma volume dropped —in Cases 3 and 5 by 2 and 4 litres respectively. The volumes in Cases 1, 3, and 4 were within normal limits, while that in Case 5 was just outside the upper limit for Africans in Kampala as reported by Leonard *et al.* (1965). The plasma volume in Case 2 remained rather high, though the haemoglobin rose from 9.5 to 14.6 g./100 ml. and the P.C.V. from 30.5 to 40.0%.

Liver Changes.—The repeat liver biopsy in Case 1 showed immature myeloid cells and occasional megakaryocytes in the hepatic sinusoids consistent with myeloid metaplasia. Difficulty was experienced in withdrawing marrow, which suggested the patient had myelofibrosis. A review of earlier liver biopsies on that patient from 1965 and 1964 showed some immature cells within the hepatic sinusoids which differed from the usual findings in big spleen disease. Re-examination of the splenectomy histology also showed the presence of immature myeloid cells, confirming the diagnosis of myeloid metaplasia. Despite this, both preoperative and postoperative studies showed a very high malarial antibody titre, and it seems possible that there were two factors accounting for the splenomegaly. Whether or not this was so, the haematological and haemodynamic results were exactly comparable to the other four cases, and so the patient has been included in this series. Liver biopsies from the other four cases showed varying degrees of lymphocytic infiltration of the liver sinusoids with some Kupffer cell hyperplasia ; these changes were not significantly different from those found in 1965. Standard liver-function tests were normal before and after splenectomy except for two slightly raised alkaline phosphatase levels in 1966. Total serum proteins have risen in all cases (see Table). In two out of the four cases for which results are available the rise is accounted for by a marked increase in the serum albumin, while in three out of four cases the serum globulin levels are almost unchanged.

Malaria and Other Studies.—No malaria parasites were found in six successive films on three patients and three successive films on two patients. In all cases the malaria antibody titre was equal to or above that found before splenectomy (see Table). Three patients had developed very light hookworm infections and two had high antibody titres to brucella, but no patient had a raised antibody titre for salmonella.

Discussion

The symptomatic and haematological improvements in these patients 15 months after splenectomy are most striking. Richmond *et al.* (1967) concluded that the improvement in the haematocrit two months postoperatively is largely due to the fall in the plasma volume. Our results confirm this and show that there has been a further improvement in the 15 months since the operation. These findings are in keeping with those of McFadzean *et al.* (1958), Cook *et al.* (1963), Weinstein (1964), and Bowdler (1967).

The immediate effect of splenectomy is to remove from the body a certain mass of red cells and plasma, but the mass of plasma contained in the spleen is quantitatively quite insufficient to account for the marked changes in the plasma volume. Neither the mechanics of the preoperative hypervolaemia nor that of the postoperative fall in plasma volume is understood. Weinstein (1964) suggested that changes in the plasma proteins and other macromolecules might be an explanation. This series is too small from which to draw any conclusions about the protein pattern ; however, there has been a rise in the total serum proteins in all cases, and in two there was a marked rise in the serum albumin level after surgery. Studies of the macroglobulin pattern in these cases are being undertaken in greater detail and will be reported later.

A number of cases of big spleen disease respond well to treatment with antimalarial drugs and show a marked symptomatic improvement and a reduction in spleen size (Hamilton, unpublished observations). It is not yet clear exactly which cases will respond in this way, but one patient with big spleen disease in the 1965 study has been on continuous antimalarial therapy for 14 months. In this time his spleen has regressed from 17.8 to 8 cm. below the costal margin. He feels better, his plasma volume has fallen from 73.1 to 46.4 ml./kg. (total from 3,380 to 1,940 ml.), and his P.C.V. has risen from 30 to

44%. His only treatment has been a 15-day course of primaquine followed by 100 mg. of proguanil daily. This is further evidence for a malarial cause of this syndrome and also for implicating the spleen in the plasma volume changes. The role of the spleen is also shown by a case of Felty's syndrome (Pengelly, 1966), in which a marked reduction in spleen size and plasma volume after corticosteroid therapy was found.

Not all patients with big spleen disease or idiopathic tropical splenomegaly respond to antimalarial therapy, and even for those cases which do respond long-term supervision may be impossible. In those patients with chronic abdominal pain, an enormous spleen, and gross dilution anaemia, splenectomy may be the treatment of choice. M. Paliwoda (personal communication, 1967) carried out 70 splenectomies for cases such as these in Uganda with an operative mortality of only 4.3%, and though the follow-up data are incomplete the patients in general seem to have done well. However, the spleens are large, and good surgical technique with wide exposure is necessary. There is a danger of overtransfusing a hypervolaemic patient and also the added risk in the tropics of patients being particularly prone to infection after splenectomy. Fatalities from *P. falciparum* after splenectomy have occurred in West Africa (Watson-Williams, personal communication). In this series, postoperatively, the patients all registered high antibody levels to malaria and two developed a high brucella antibody titre; however, none seem to have suffered from significant clinical malaria. Against these dangers must be set the marked improvement in the well-being of these patients, who were able to return to doing a normal day's work after splenectomy.

Summary

The clinical and haematological effects of splenectomy on five Ugandan patients with "big spleen disease" were studied 15 months after operation and the results compared with those obtained preoperatively.

All patients were symptomatically much improved and they all showed a marked improvement in their haemoglobin and P.C.V. levels. Before operation the patients had marked hypervolaemia and dilution anaemia, but after splenectomy the plasma volumes had returned to normal in three patients and in two were still slightly raised. One patient had developed evidence of myelofibrosis, but the others showed no marked change in liver biopsy appearances.

There were no untoward effects of splenectomy and no acute attack of malaria was described, though the malaria antibody titre had been maintained or raised.

We are grateful to Professors A. W. Woodruff, J. A. Tulloch, and W. A. Parson for their encouragement and criticism, and to Dr. G. Cook and Dr. D. Wykoff for their help in this study. Financial support was provided by the Leverhulme Trust, the World Health Organization, and the U.S. Army Medical Research and Development Command, Department of the Army, under Research Grant Number DA-MD-49-193-63-6101.

Splenectomy in Tropical Splenomegaly

D. S. PRYOR,* M.B., B.S.

Brit. med. J., 1967, **3**, 825–828

Massive splenomegaly of uncertain cause is frequent in New Guinea and is particularly prevalent in the Upper Watut Valley, 50 miles (80 km.) south-west of Lae, where over 80% of the inhabitants of some villages have enlarged spleens (Pryor, 1967a). Though idiopathic tropical splenomegaly occurs in areas where malaria is endemic (Hamilton *et al.*, 1965), a causal relationship has not been established. The villages of the Upper Watut are situated at 3,000 to 5,000 ft. (914 to 1,524 m.) above sea level, malaria is endemic, and the incidence of splenomegaly decreases at the highest altitudes. Other causes of tropical splenomegaly such as leishmaniasis, schistosomiasis, haemoglobinopathies, and hepatic cirrhosis can be excluded in these patients. The natural history of the disorder in this area is not known, but though enlargement of the spleen is often very great it appears to be a relatively benign condition causing little disability in the majority of individuals.

Anaemia, leucopenia, and thrombocytopenia are commonly associated findings, but haemoglobin values as low as 5 g./100 ml. may occur without apparent disability. A raised reticulocyte count is usual, and studies with radiochromium-labelled cells demonstrate a shortened red cell life-span with evidence of excessive red cell destruction in the enlarged spleen (Pryor, 1967b). However, the main cause of the low haemoglobin value is a greatly expanded plasma volume, which may be more than twice the normal value.

A few individuals complain of symptoms of anaemia or pain and discomfort due to the size and weight of the spleen. Splenectomy has been performed in 15 patients who had disabling symptoms, and the results form the basis of this report.

Methods

Selection of Patients.—Twelve of the 15 patients requested splenectomy and the other three were similar patients with disabling symptoms. Twelve patients were from the Watut Valley and the remainder from villages in the Lae medical region. Eleven were males and four were females aged from 10 to 45 years (Table I). In each case the spleen was enlarged to below the umbilicus and in nine cases it extended into the right iliac fossa. All had an enlarged liver with a smooth firm edge. Ten patients had precordial systolic murmurs and 10 had raised jugular venous pressures. Less frequent signs were dependent oedema, leg ulceration, and mild jaundice. In all cases chest *x*-ray examination showed moderate enlargement of the heart with prominent pulmonary vascular markings.

---

* Haematology Research Unit, Angau Memorial Hospital, Lae, New Guinea. Present address: the Prince Henry Hospital, Little Bay, New South Wales, Australia.

Laboratory Techniques.—Standard haematological techniques were used (Dacie and Lewis, 1963). Radiochromium-labelled red cell studies were carried out by a modification of the method of Crawford and de Gruchy (1958). Plasma volume was measured with radioiodine (^{131}I)-labelled human serum albumin (Veall and Vetter, 1958).

Results

Haematological Findings

The preoperative haematological findings are recorded in Table I. All patients were anaemic, with haemoglobin values ranging from 4.8 to 11.1 (mean 7.3) g./100 ml. Reticulocyte counts ranged from 6.6 to 23.3 (mean 11.3)% and white cell counts from 1,400 to 5,500 (mean 3,700)/cu. mm. All had thrombocytopenia, platelet counts ranging from 21,000 to 117,000 (mean 54,000)/cu. mm.

Various measurements with radioactive isotopes were performed preoperatively on 12 individuals (Table II). Red cell survival was measured in six subjects, ^{51}Cr-labelled autologous red cells being used. The half-life ranged from 9 to 19 (mean 13) days, the normal range in New Guinea natives without splenomegaly being from 25 to 30 days (Pryor, 1967b). Despite the low haemoglobin values, the red cell volume measured with ^{51}Cr-labelled red cells was normal or raised, the volumes in 12 subjects ranging from 24.0 to 51.2 (mean 35.5) ml./kg. The normal range in New Guinea natives is similar to that in Caucasians—that is, 23 to 35 ml./kg. (Pryor, 1967b). Plasma volume measurements with ^{131}I-labelled albumin in nine subjects gave high values ranging from 76.5 to 115.0 (mean 93.3) ml./kg., the normal range being 40 to 50 ml./kg. (Dacie and Lewis, 1963).

Preoperative Management

During investigations in hospital the patients received a course of chloroquine (600 mg. of chloroquine base followed by 300 mg. on the first day, 300 mg. daily for two further days, and 300 mg. weekly), ferrous sulphate 300 mg. three times daily, and a course of 5 g. of bephenium hydroxynaphthoate (Alcopar) daily for three days. Patients were also given individual treatment such as diuretics for oedema and antibiotics for urinary or chest infections. In view of the increased blood volume, transfusions of packed red cells were given to achieve a haemoglobin level of about 9 g./100 ml. only. Eleven patients received an average of 4 units of packed cells (1 unit being equivalent to 400 to 500 ml. of whole blood) and four received none. The packed cells were given within two days of operation, since transfused cells have a short survival time in these patients and the haemoglobin level falls quickly after transfusion (Pryor, 1967a).

Operation

The peritoneal cavity was opened through an abdominal incision and at least 200 ml. of clear fluid was found in each case. The liver was enlarged in all, with prominent left lobe enlargement in two cases. The splenic blood vessels were large and not tortuous, curving down over the tail of the pancreas to reach the large splenic hilum. A systolic thrill was palpable over the vessels in two cases, one of which had had an audible bruit over the spleen before operation. Adhesions between the spleen and adjacent parts proved a major difficulty only once (Case 11). Splenic vein pressures were measured at operation in five cases with a simple glass manometer filled with sterile isotonic sodium citrate solution. The results ranged from 12 to 20 (mean 18) cm., normal values being from 4 to 19 cm. (Atkinson and Sherlock, 1954).

Considerable shrinking of the spleen followed ligation of the splenic artery, and this facilitated the subsequent dissection and delivery of the organ, also producing an autotransfusion of

TABLE I.—*Results of Routine Haematological Tests Before and After Splenectomy in 16 Cases of Tropical Splenomegaly*

* Where plasma volume was measured more than once after splenectomy, the last result is given. The other results may be seen in the Chart.

blood at this stage of the operation. Operative blood loss was replaced by transfusion of whole blood so that the haemoglobin level immediately after operation was higher than before.

Postoperative Complications

Four patients required transfusion for postoperative bleeding, in two of whom re-exploration of the abdomen was carried out. In one (Case 2) further ligation of the splenic artery stopped the bleeding, and the other (Case 11) died after continuous bleeding from the diaphragm and liver, which had been densely adherent to the spleen. Wound infections occurred in five cases but did not cause serious morbidity. Three patients had chest infections in the postoperative period and one had malaria due to *Plasmodium vivax* six weeks after operation. Two patients had marked dependent oedema and ascites after operation, which gradually subsided over about eight weeks.

Pathology of Spleens and Livers

The spleens weighed 2,090 to 4,380 (mean 3,270) g. Even after removal as described, almost 1 litre of blood ran from the spleen in two cases when the clamps were removed from the vessels. The spleens were firm in consistency, with rounded edges and one or two distinct notches on the medial border. The capsules were normal except for some patchy thickening in three cases. The cut surface of the spleens was a uniform dark red ; no infarcts were seen though one specimen showed a subcapsular scar. The Malpighian bodies were not visible.

Microscopical examination of the splenic tissue revealed greatly dilated sinuses with reticuloendothelial hyperplasia and marked erythrophagocytosis. There was atrophy of the Malpighian bodies, a paucity of fibre, and no malarial pigment.

In 11 patients microscopical examination of a wedge biopsy of the liver showed sinusoidal dilatation, Kupffer cell hyperplasia, and lymphocytic infiltration of sinusoids and portal tracts, but no cirrhosis. The morphology of these livers and spleens has been reported in detail by Pitney *et al.* (1967).

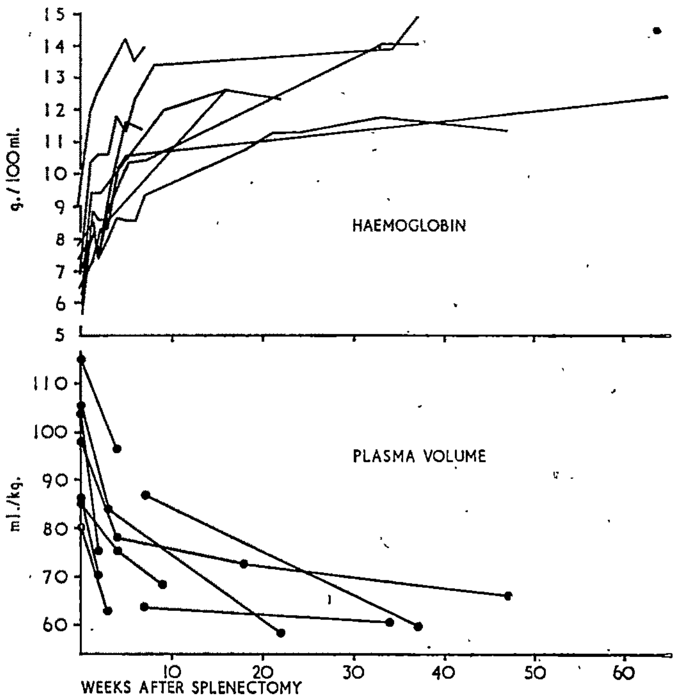
Results of Splenectomy

Four patients were well 14 to 18 months and four at two to nine months after operation. Only a short time had elapsed since splenectomy in two cases. One Watut patient died the day after operation from uncontrolled haemorrhage, as described above, and two males (Cases 8 and 13) died of acute illnesses in the village five and three months after operation, respectively. Two patients had malaria due to *P. vivax* four and six months after operation, and two others had pneumonia while under observation, four and eight months after operation. One man had acute gouty arthritis three weeks after operation, and after four months was admitted to hospital with cervical tuberculous lymphadenitis, which responded well to chemotherapy. Two of the three patients not belonging to the Watut area have been lost to follow-up. Thus of 11 patients followed for more than two months, eight were well and three had died—one as a direct result of operation and two from unknown causes.

Effect of Splenectomy on the Haematological Findings

In each case splenectomy was followed by a rise in haemoglobin (Table I). An initial temporary rise was related to blood transfusion and was followed by a gradual rise over several months (see Chart). Reticulocyte counts fell after one to two weeks to a mean of 1.4% (range 0.4 to 2.6%). Howell–Jolly bodies and target cells were seen in the peripheral blood as early as 24 hours after operation. White cell counts rose promptly and a temporary leucocytosis often developed, final counts ranging from 6,000 to 19,700 (mean 10,600) cu. mm. Platelet counts rose in the first two weeks, in three cases to over 1,000,000/cu. mm. and in one case to over 2,000,000/cu. mm., finally reaching a mean of 335,000/cu. mm.

Red cell volume and red cell survival studies were repeated in three cases and normal values were obtained (Table II) except in Case 2, and this man was studied only 16 days after splenectomy, before equilibrium had been reached after massive blood loss and transfusion. Plasma volume studies were made in 10 cases at various times after splenectomy. There was a steep fall from the high preoperative level and a subsequent slow fall continuing over several months (see Chart). In the first four to eight weeks weight loss was marked (mean 5.9 kg. for seven cases), but this was subsequently recovered, to result in a final gain in weight (mean 3.2 kg. for five cases). Therefore the absolute plasma volume fell even more than is shown with the volume expressed in ml./kg. of body weight.



Effect of splenectomy on haematocrit and plasma volume in cases of tropical splenomegaly.

Discussion

In this group of patients with tropical splenomegaly, splenectomy produced correction of the anaemia and relief of symptoms. The main cause of the sustained rise in haemoglobin value was the progressive fall in plasma volume. Though increased red cell destruction occurred preoperatively and was corrected by splenectomy, haemolysis was not an important cause of anaemia, since the red cell volume was often raised and usually fell after splenectomy. The reason for the high plasma volume and its correction by splenectomy is not known. Similar results were recorded by McFadzean *et al.* (1958) in cryptogenic splenomegaly in Hong Kong and by Prankerd (1963) and Bowdler (1963) in patients with splenomegaly associated with blood disorders. In the present cases hypervolaemia was possibly related to hyperimmunity to malaria or other antigens causing increased rates of globulin synthesis. Splenectomy may have caused a decrease in globulin synthesis, giving rise to the fall in plasma volume. The lower red cell volume after splenectomy probably occurs because red cell production no longer has to maintain a large volume of cells in the splenic red cell pool (Prankerd, 1963 ; Weinstein, 1964 ; Pryor, 1967b).

It is generally recognized that splenectomy, at least temporarily, increases susceptibility to bacterial infections (Lowdon *et al.*, 1966) and in the present small series several infections occurred after splenectomy. The findings in a large number of splenectomies in Hong Kong were similar (Cook *et al.*, 1963). The two patients who died suddenly in their villages some months after operation may have succumbed to overwhelming bacterial infections or to malaria. No clinical observations could be made during their fatal illnesses. Splenectomy alters the effective state of immunity to malaria, and in latent infections in experimental animals parasitaemia induced by splenectomy may persist for life (Garnham, 1963). Fatal *Plasmodium falciparum* malaria has been demonstrated after splenectomy in a previously immune chimpanzee (Rodhain and Jadin, 1964). *P. vivax* parasitaemia occurred in the postoperative period in one patient and some months after operation in two. Chloroquine tablets were given to each patient, with instructions that they be taken if fever occurred. Therefore little information concerning the hazards of malaria after splenectomy is provided. However, for cases from areas with endemic malaria and sporadic medical surveillance, splenectomy should probably be restricted to patients with disabling symptoms. Most persons with tropical splenomegaly are not greatly disabled despite their very large spleens and considerable anaemia.

The microscopical appearances of the liver biopsy specimens confirmed the absence of hepatic cirrhosis (Pitney *et al.*, 1967), so that the results of operation might be expected to be better than those of Chaudhuri *et al.* (1956) and Cook *et al.* (1963), where many patients had cirrhosis. This latter study also showed much less mortality after splenectomy in those patients without cirrhosis. Hepatomegaly is usually found in tropical splenomegaly and, as jaundice, wasting, and even oedema may occur, it is difficult to exclude cirrhosis other than by liver biopsy.

Summary

The results of splenectomy are described in 15 patients with tropical splenomegaly in New Guinea. Splenectomy was performed only in those patients with disabling symptoms due to anaemia or the size and weight of the spleen. There was one operative death due to haemorrhage, and two other patients died suddenly some months after splenectomy.

The main cause of anaemia in this disorder was an expanded plasma volume, which was reduced after splenectomy. Increased red cell destruction was also corrected by splenectomy. There was a sustained rise in haemoglobin values, and the surviving patients have remained well over a short follow-up period. It is suggested that, until more information is available concerning the natural history of the disorder and the long-term results of splenectomy in regions where malaria is endemic and suppressive therapy difficult to administer, splenectomy should be reserved for patients with disabling symptoms.

I wish to thank Professor W. R. Pitney, of the University of New South Wales, for helpful advice and criticism; Dr. A. R. Shepherd, who performed the splenectomies; the Wellcome Trust for the provision of equipment; and Dr. R. F. R. Scragg, Director of Public Health, Territory of Papua and New Guinea, for making available facilities for this work.

Joint Haemorrhage in Haemophilia: Is Full Advantage Taken of Plasma Therapy?

ANITA M. ALI,* M.B., B.S.; R. H. GANDY,*† M.B., B.S.; MARGARET I. BRITTEN,* B.SC.
KATHARINE M. DORMANDY,* M.B., M.R.C.P., M.C.PATH.

Brit. med. J., 1967, 3, 828–831

Recurrent bleeds into joints and muscles are among the most typical and frequent of the haemorrhages sustained by the severely affected haemophiliac (Wilkinson *et al.*, 1961; Ramgren, 1962; Biggs and Matthews, 1966; Stuart *et al.*, 1966; and many others). Without immediate and competent treatment these bleeds are potentially crippling, leading to various degrees of functional disability (Jordan, 1965a); their frequency makes adequate schooling practically impossible (Britten *et al.*, 1966), thereby jeopardizing the boy's future career.

Despite the fact that plasma replacement therapy, given as soon as possible after the onset of bleeding, has for some years been the accepted treatment for musculoskeletal haemorrhage (Biggs, 1964; van Creveld, 1964; Hardisty and Ingram, 1965; Salzman and Britten, 1965), it was apparent that many haemophiliacs in the Metropolitan Regional Hospital Board Areas were receiving inadequate treatment or none at all. A survey was therefore undertaken to ascertain the extent to which this treatment was in fact being used in that area. An attempt was also made to correlate the outcome of bleeds with the therapy that had been received. This paper describes our findings during 1965 and 1966.

Materials and Methods

The patients and their parents who took part in this investigation were already in touch with us through our survey into the educational problems of haemophiliacs. A total of 210 patients under the age of 30 ("boys"), registered at many different hospitals and all suffering haemarthroses, agreed to co-operate.

---

* Department of Haematology, the Royal Free Hospital (North-western Branch), London N.W.3.

† Present address: Department of Pathology, the Combined Cambridge Hospitals, Tennis Court Road, Cambridge.

The boys were usually visited at home, with one or both parents present. A detailed medical history, with particular reference to the musculoskeletal system, was taken and the patient's joints were examined. The range of each joint was assessed on the active movements which the boy could accomplish without difficulty or pain. The degree of muscle-wasting was noted.

Haemophilia and Christmas disease were considered together. The patients were divided into groups according to age and the treatment received.

The age groups chosen were 0 to 5 years, 5 to 11, 12 to school-leaving, and school-leaving to 30. (School-leaving age was used in preference to a definite age, because the hazards of the schoolboy differ from those of the young adult.)

The treatment groups chosen were "no plasma" and "plasma." Boys were assigned to the no plasma group if they had never or only rarely received replacement therapy, and to the plasma group if they regularly or frequently received it. Their treatment was regarded as prompt if they received a rapid infusion of fresh-frozen plasma or its equivalent within 12 hours of the onset of a joint or muscle haemorrhage.

A system of grading, based on that of DePalma and Cotler (1956), was used for all joints into which there had been a haemorrhage. The assessment was clinical, as no radiological examinations were made. Thus:

Grade 1—joints into which there had been one or more bleeds but which showed no residual decrease in the range of movement and therefore no deformities which could be clinically observed.

Grade 2—joints showing slightly reduced range of movement but no appreciable joint dysfunction.

Grade 3—joints in which the reduced range of mobility interfered with function.

Grade 4—joints showing more advanced changes than in grade 3—that is, severe deformities.

Results

Of the 210 boys 196 sustained numerous episodes of joint haemorrhage; 131 were found to have deformities. Haemorrhage had occurred into 999 joints, of which 415 were deformed. Of the affected joints, 38% had sustained first bleeds before the boys had reached the age of 4, and 60% had done so by the age of 6.

A quarter of the boys under the age of 5, nearly half of the 5–11 group, and the majority of the older boys had deformities. Table I shows not only how early haemophilic deformities begin but how rapidly their severity increases during the years of growth. Several of the boys in the school-leaving to 30-year group had spent a period of their childhood confined to wheelchairs because of severe knee deformities. All of these had had orthopaedic treatment and were able to walk again.

Varying degrees of muscle-wasting, especially in the thigh and calf, were seen in most of the boys. Where there was gross quadriceps-wasting the boys appeared to have knee-bleeds with ever-increasing frequency unless the knee had been protected by a calliper or other appliance. Muscle haemorrhages accounted for five equinus deformities resulting from calf bleeds, one claw-hand after a forearm bleed, and one fixed flexion deformity of the left elbow after a haemorrhage into the biceps.

Though temporary immobilization, preferably by means of splints, is an important aid to recovery from haemarthroses and muscle bleeds, as is graded physiotherapy (France and Wolf, 1965), many of the boys had never had a joint splinted nor had they been taught suitable exercises to maintain the muscles controlling the affected joint.

TABLE I.—*Deformed Joints. Percentage of Lesions of Grades 2, 3, and 4 in Each Age Group.*

Deformities	Age Groups

" " 4	0	15	20	20

* SL=School-leaving age.
N.B.—Grade 1 lesions are omitted because they are not deformities.

Plasma Replacement Therapy

Extent of Use

Table II shows the division of the boys into age and treatment groups. Seventy-one boys did not attend hospital for haemarthroses; 29 others went to hospital but were not infused, and 16 had had plasma only once or twice in their lives. Three boys had inhibitors to factor VIII; the histories of the remaining 16 classified as "miscellaneous" were vague.

TABLE II.—*Treatment Received by the Boys Up To the Time of the Survey*

Treatment	Age Groups				Total
	0–4	5–11	12–SL*	SL–30	
Plasma Prompt	7	6	12	4	29 } 75
Plasma Delayed	7	7	25	7	46
No plasma	12	48	30	26	116 } 135
Miscellaneous†	0	3	15	1	19
Total	26	64	82	38	210

*SL=School-leaving age.
† "Miscellaneous" includes boys known to have had some plasma therapy but for whom no detailed history could be obtained and 3 with inhibitors to factor VIII.

Of the 210 boys, only 75 had received plasma with any regularity; the treatment of 46 of these had been delayed, leaving only 29 who appeared to be receiving prompt and regular therapy.

Reasons for Delayed Treatment.—(a) Delay on the part of the patient or his parents in seeking hospital treatment: 55 boys did not go to hospital within 12 hours of the onset of a haemarthrosis; half of these waited several days or even longer. (*b*) *Delay in obtaining admission to hospital*: about 26% of the boys contacted their general practitioners before going to hospital. Sometimes this was because their hospitals insisted on a doctor's letter each time; others relied on him to arrange transport. Further delays occurred on arrival at many hospitals, where there were no short cuts through the time-consuming process of admission and a haemarthrosis was not regarded as an emergency. (*c*) *Delay in hospital before an infusion was given*: 16 boys were not treated on admission; of these, 14 waited several days.

Short-term Effects of Plasma Therapy

In addition to the rapid relief of pain and the faster reduction of swelling, plasma treatment considerably shortened the time "out of action." Thirty-nine boys gave estimates of the periods of time they were incapacitated by haemarthroses treated with plasma and those not so treated. A further 44, who did not receive plasma for joint bleeds, estimated the time missed with each episode. Of those treated, 72% were active in less than a week, and none were laid up for more than two weeks, whereas 52% of the untreated boys were out of action for two to four weeks and 7% for over four weeks. Only boys with very minor haemarthroses recovered untreated in less than a week.

Long-term Effects of Plasma Therapy

Fourteen boys, all under the age of 8, had received plasma treatment throughout their lives. Among their 40 affected joints there were only three deformed ones, two of which were in the same child. Both these boys had had treatment only after delays of two days. Two of the deformities were grade 2 and the third grade 3.

A detailed comparison was made between the numbers of new deformities which had developed in treated and untreated boys between the ages of 5 and school-leaving; this was the period during which the maximum number of deformities had been found to start. Our findings were:

Untreated boys: 1 deformity to every 7 joints with haemorrhage.
Treated boys: 1 deformity to every 39 joints with haemorrhage.

We obtained the above figures in the following way: All boys in the no-plasma group who sustained recurrent haemarthroses in more than one joint were considered, as were all similarly affected boys in the plasma group, provided that they had been receiving treatment for at least three years.

The average age of the 26 treated boys was 11.1 years (range 5–17), and they had been receiving treatment for an average of 4.5 years (range 3–7). Only four deformities had developed in the 156 affected joints. Three of these had occurred in boys who had received delayed infusions. The fourth, a grade 2 knee lesion, appeared to have been promptly treated for each haemarthrosis, but this joint had sustained many haemorrhages in a short period. The average age of the 50 untreated boys was 11.3 years (range 5–17). Records were made of all deformities that had developed in these boys in the 4.5 years before their examination for the survey. Thirty-six deformities had started in the 251 affected joints.

Haemarthroses occurred to approximately the same extent in the two groups both before and during the period studied; before that time the incidence of deformity had also been similar.

Thirty-three boys said that on one or more occasions aspiration had been used in the treatment of massive haemorrhage into a knee or ankle. In some cases joints had unfortunately been aspirated without plasma cover. Where plasma had been given in conjunction with aspiration some boys had felt great relief, but for others this procedure had been unsuccessful and painful.

Nearly half of the boys were not registered at a haemophilia centre, though there were 10 in the area investigated. Many of those who were registered had attended only for diagnosis and were treated at other hospitals or at home. One severely crippled boy of 20 had never been to any hospital for a haemarthrosis.

Discussion

Many authors have reported a big reduction in the incidence of deformity in patients receiving plasma replacement therapy (Biggs, 1964; Poulain, 1964; Ahlberg, 1965; Jordan, 1965b; Brinkhous *et al.*, 1966). As the results of our survey were similar, it was disturbing to find how few were the boys receiving prompt, or indeed any, plasma treatment for joint and muscle haemorrhages.

Since many of the affected joints examined had sustained first bleeds before the boys had even reached the age of 4, it is clear that the best therapy must be available from earliest childhood if permanent deformity is to be prevented. This applies equally in cases of muscle haemorrhages, as the deformities which follow these are usually severely disabling—none of those seen in the survey had been promptly treated.

Effective treatment involves the early administration of active therapeutic material. Day or night the patient or his parents must themselves be able to telephone the hospital to say he is coming for an infusion. As plasma infusions are given rapidly (Matthews, 1966) treatment can often be on an out-patient basis, thus causing minimal interruption to the boy's life. Evans (1967) has commented that most of the haemophilic boys at the Lord Mayor Treloar College, Froyle, Alton, Hampshire, where there are more than 30 over the age of 11, are absent from school with a haemarthrosis for hours instead of weeks now that they are receiving prompt plasma therapy.

At the time of the survey much of the frozen plasma issued to hospitals in the south-east of England was deficient in factor VIII, and therefore useless for the control of haemophilic haemorrhage (Bennett *et al.*, 1967). Because their own tests had shown the poor quality of this plasma, several haemophilia centres were making their own therapeutic materials (personal communications from R. M. Hardisty, 1966; C. A. Holman, 1966; and G. I. C. Ingram, 1966). All the 29 boys thought to be having prompt and effective treatment attended one of those centres. It seems likely that the use of inactive plasma, as well as delayed administration, was responsible for the lack of success of the therapy received by some of the boys.

Because haemophilia is a rare disorder, and its management is highly specialized, it is desirable that patients should be treated only at hospitals where every facility is always available. Many patients have found it worth while to go to a centre for treatment even when a considerable journey was involved. Where it would be impracticable for a boy to attend a haemophilia centre for routine treatment, his local hospital should co-operate closely with the centre where he is registered, so that advice can be easily obtained at any time (Dalrymple-Champneys *et al.*, 1967).

The majority of doctors have little chance to gain experience in the treatment of haemophilia. Many did not seem to appreciate the seriousness of joint and muscle bleeds, and were unaware of the great advances made for the treatment of these. Discouraged by the results of the conservative care given by many hospitals, general practitioners often merely advised bed-rest. It was evident during the survey that much needless suffering and crippling was occurring because doctors, parents, and patients did not know where to seek help.

This country has been well to the fore, both technically and clinically, in research into the problems of haemophilia, as was indicated in a leading article in the *British Medical Journal* (1966). It would indeed be sad if Great Britain were to lag behind in the treatment of the most frequent complications of the disorder. For practical reasons we had to limit the area studied, and have therefore made no mention of the position in other parts of the country, though we are well aware that a number of coagulation units are providing excellent care for their haemophilic patients. Now that cryoprecipitate factor VIII concentrate is becoming more readily available it should be easier to organize the provision of good therapy, and on a wider scale, than it was before 1966. It is essential that knowledge of the advantages of this treatment, and of where it can be obtained, should be more widespread among both doctors and patients.

Summary

The state of the joints of 210 haemophilic boys was clinically investigated in south-east England during 1965–6. Particular attention was paid to the treatment that had been received.

Prompt infusions of active plasma preparations had reduced (*a*) the duration of incapacity from haemarthroses by over half, and (*b*) the incidence of new deformities by four-fifths.

Without plasma therapy joint damage begins at an early age—one-quarter of the boys under 5 years had deformed joints. Overall, 131 boys had deformities involving 415 joints.

Only one-third of the 210 boys had received any plasma therapy; only one-seventh had had prompt treatment.

Some of the reasons why so few boys had had effective treatment were: (*a*) many doctors and parents were unaware of the benefits of plasma therapy for haemarthroses or of the need for prompt infusions; (*b*) few hospitals had arranged for patients' transport and speedy admission—few had issued instructions or given advice; and (*c*) many haemophiliacs attended hospitals which had no specialized coagulation units.

We wish to thank the many consultants, general practitioners, school medical officers, and school principals who have made this survey possible. We are especially grateful to Dr. Rosemary Biggs for her help in planning the survey and in interpreting the results. The co-operation of patients and their parents has been unlimited.

Financial support was given by the Medical Research Council and the Haemophilia Society.

Our preliminary findings were reported by K. M. D. to the Institute of Haemophilia during the 10th World Congress of the International Society for the Rehabilitation of the Disabled, Wiesbaden, September 1966.

Trial of Gastric Cooling for Haematemesis*

J. B. McFARLAND,† M.D., CH.M., F.R.C.S.; J. G. GOW,‡ M.D., CH.M., F.R.C.S.

Brit. med. J., 1967, **3**, 831–834

Gastric cooling as a method of controlling upper gastrointestinal haemorrhage was initially developed by Wangensteen *et al.* (1958). The temperature and the rate of flow of coolant which they employed produced an intragastric temperature of the order of 15° C. They suggested that this caused: (1) reduced gastric blood flow; (2) depressed acid/pepsin secretion and activity; and (3) decreased gastric motility.

In an extended clinical series they reported on the treatment of 75 patients by gastric cooling, with control of haemorrhage in 57 (76%) (Nicoloff *et al.*, 1962). This result is comparable to the figures analysed by Crampton *et al.* (1964), who added a further 123 reported cases and noted an overall control of haemorrhage in 72.6%. Unfortunately, cessation of haemorrhage cannot necessarily be equated with patients' survival, and in one of the large series included in this analysis (Wangensteen *et al.*, 1963) haemorrhage was controlled in 87% of cases but the hospital mortality was 57%.

Usually a commercial refrigerator formed the basis of the apparatus for gastric cooling. A refrigerated alcohol/water solution was pumped through an intragastric balloon. Mechanical complications with such apparatus have been described by Wangensteen (1962), Nicoloff *et al.* (1962), Richman and Anthony (1963), and Miller *et al.* (1963). Because of these complications a simplified water-circulating apparatus was used in this study.

Haematemesis is an alarming symptom of a serious situation. There is a definite place for a non-operative technique that would assist in its early management and allow time for an exact diagnosis to be made later. We here compare a trial of early gastric cooling with conventional methods of managing massive gastrointestinal haemorrhage.

Subjects, Materials, and Methods

The patients treated had been admitted urgently to a general hospital after a haematemesis or melaena. The condition was thought to be serious enough for the subject to be included in the series if one or more of the following features were present: (1) haematemesis in excess of 1,000 ml., observed by a competent medical witness; (2) fall in systolic blood pressure to 100 mm. Hg. or below for one hour or longer; and (3) acute fall in haemoglobin to below 10.2 g./100 ml. or haematocrit to below 30%.

The patient was admitted to a special unit in a surgical ward, and after he had been assigned to an age group (under or over 50 years) a random selection was made for treatment to include gastric cooling or to be by conventional methods.

The policy of the conservative management is indicated by the following points:

(1) Blood was replaced intravenously at a rate and to an amount indicated by the patient's condition. The blood pressure, pulse rate, haemoglobin, and haematocrit were used as guides, though less importance was given to the latter two in the later stages.

(2) Intravenous dextrose/saline was given slowly (500 ml. six-hourly), usually to keep an intravenous drip infusion open.

(3) A nasogastric tube was *not* used during conservative management and was introduced only if operation (or gastric cooling) was planned.

(4) The patient was encouraged to take milk-and-water orally during conservative management (and immediately after a period of gastric cooling).

(5) Sedation, usually by intramuscular injection, was used as indicated. The drug used was decided for each patient individually: morphine, Omnopon, and a combination of chlorpromazine 25 mg. with promethazine 25 mg. were most commonly given.

(6) Antibiotics, usually by injection, were given when specifically indicated or when cover appeared particularly valuable.

Half the patients in the series were managed conservatively. For the other half gastric cooling was used in addition.

A few days subsequent to this treatment a barium-meal or Gastrografin *x*-ray examination was carried out.

Gastric Cooling Apparatus

The cooling unit in this study was the Cryocycle hypothermia system (Fig. 1). This consisted, in principle, of a pump which circulated water at a rate of about 2 litres a minute in a closed system through copper pipes in an ice-bath, and by tubes to the intragastric balloon. A double balloon of extremely thin (condom) rubber was used with a thermistor lying between the balloons. The cooled water entered through the centre of the coaxial tube, was ejected laterally into the balloon, and returned through the outer tube.

† Senior Lecturer in Surgery, University of Liverpool.

‡ Consultant Surgeon, Liverpool Regional Hospital Board.

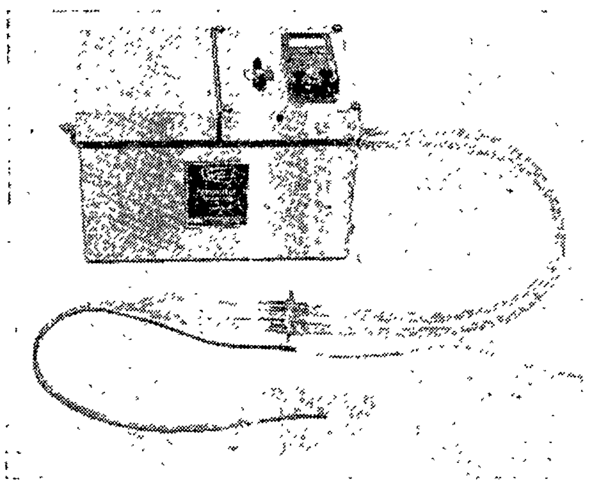

Fig. 1.—Photograph of the Cryocycle hypothermia system. A thermistor lies between the two thin walls of the double balloon, which has been filled with 800 ml. of water.

Technique of Gastric Cooling

When the decision to employ gastric cooling had been made the patient was usually sedated with promethazine 25 mg. and chlorpromazine 25 mg., given intramuscularly. A local anaesthetic spray of 4% lignocaine was used to numb the patient's throat. A nasogastric tube was passed and the patient's stomach was thoroughly lavaged with cold water. This was continued right up to the time for the gastric cooling balloon to be passed, when the nasogastric tube was withdrawn. Every effort was made to empty the stomach completely, especially to remove all blood clot and thus allow good contact between the balloon and the mucosa.

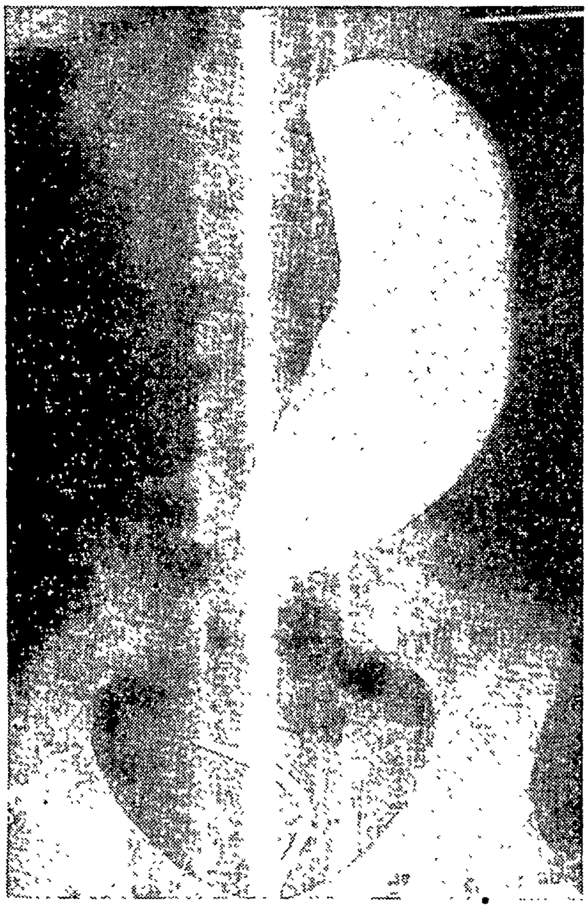

Fig. 2.—Radiograph showing a balloon filled with radio-opaque fluid in a normal stomach. Part of the thermistor lead may be seen in the stomach. The lower thermistor is in the rectum.

The length of the tube to be passed was gauged roughly against the patient, and the tube was then slowly but steadily introduced. It was most important to have the suction ready for immediate use from this point and to aspirate any regurgitated mucus or blood. The passage of the balloon was usually not difficult, but was of course easier in edentulous subjects. With the balloon and the tubes in position they were filled with 800 ml. of water in 50-ml. increments from a special syringe.

As a routine the position of the balloon was checked by one straight radiograph of the abdomen shortly after the beginning of treatment. The thermistor lead served as a guide to the position of the balloon. If more accurate visualization of the balloon was required a radio-opaque solution, such as Hypaque, could be introduced into it. Fig. 2 shows the *x*-ray plate obtained in this way from a normal-sized stomach.

When the gastric cooling was under way the pump circulated the water through the closed system of the tubes, the balloon, and the pipes in the bath. Supervision of the hypothermia machine required only that the bath was maintained with water and ice to a level covering the pipes. Carbon dioxide ice (" dry ice ") was added as a " booster " ; this was not essential, but it conserved the amount of ice used (over 1 cwt. (50.8 kg.) in 24 hours).

During the period of gastric cooling the intragastric, rectal, bath, inflow, and outflow temperatures were monitored (Fig. 3). Pulse rate, blood pressure, and respiration were recorded hourly ; electrocardiography was carried out ; haemoglobin and haematocrit estimations were done at regular intervals ; the bleeding- and clotting-times were measured once ; and the blood urea and electrolytes were estimated daily. Urine volume was recorded, checks being made on specific gravity and urea concentration.

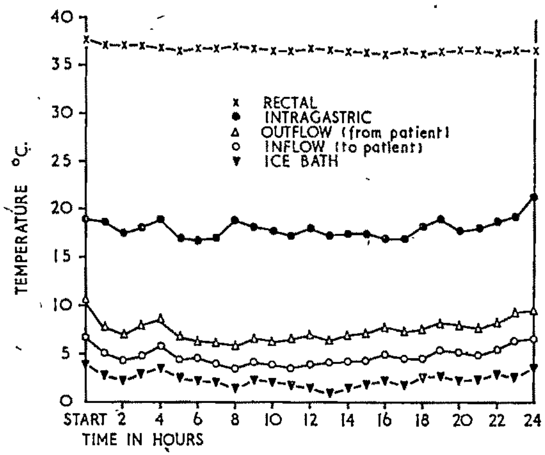

Fig. 3.—Graph of the temperatures during gastric cooling. This was compiled by averaging the figures for 10 cases early in the series.

In almost all cases gastric cooling was continued for 24 hours. Soon after it was under way the patient was covered by an electric blanket (in addition to ordinary blankets), and this was switched on as soon as any shivering or tendency of the rectal temperature to fall was noted. The level of external warming was aimed at limiting the fall in rectal temperature to only a few degrees, and sometimes a second electric blanket was required. At the completion of the period of gastric cooling the pump was switched off and the intragastric temperature allowed to level out with the body temperature. The balloon was emptied and removed.

Results

This paper describes the outcome in 44 patients treated within a two-year period. The apparent causes of the haemorrhage in this series are indicated in Table I.

Table II gives the overall outcome in the broad terms of complete recovery, successful operation, or death in each group. All hospital deaths are shown, and these are further summarized in Table III.

Table IV indicates the degree of success or failure of arrest of haemorrhage (indicated by absence of melaena, clear gastric contents, and haemoglobin level) in association with gastric cooling. This is for six patients under 50 years old (all successfully treated) and 16 over 50 years old. There was permanent success in 19 (86%) of the 22 cases.

TABLE I.—*Haematemesis: Diagnosis in 44 Cases*

	Gastric Cooling		Conservative Management		Total
Age Group:	Under 50	Over 50	Under 50	Over 50	
Gastric ulcer ..	1	9		4	14
Duodenal ulcer ..	2	4	4	6	16
No lesion on barium meal	3	2	2	4	11*
Varices		1		1	2
Carcinoma				1	1
Total	6	16	6	16	44

* This category includes 10 women, of whom two had taken salicylates, two were on corticosteroid therapy, and six remained undiagnosed. The one man had had a perforated duodenal ulcer six years earlier.

TABLE II.—*Eventual Outcome in the Series of 44 Patients*

Outcome	Gastric Cooling		Conservative Management		Total
	Under 50	Over 50	Under 50	Over 50	
Complete recovery..	5	10	6	11	32
Successful operation:					
Elective	1	1			2
Emergency ..		1		1	2
Death:					
No operation ..		3		1	4
Operation ..		1		3	4

TABLE III.—*Causes and Times of the* 8 *Deaths in the Series of* 44 *Patients*

Gastric Cooling

A.B.: 64 years, male, cardiac infarction; during G.C.
C.D.: 56 years, male, hepatic failure; one month after G.C.
E.F.: 66 years, female, stroke and cardiac infarction; 12 days after G.C.
G.H.: 64 years, male, cardiac infarction; 11 hours after G.C.

Conservative Management

S.T.: 70 years, male, cardiac failure and continuing haemorrhage; four days
U.V.: 58 years, male, hepatic failure; 27 days
W.X.: 78 years, female, post-gastrectomy leak and cardiac infarction; 18 days
Y.Z.: 68 years, female, leak after near-total gastrectomy for carcinoma; 8 days

TABLE IV.—*Degree of Success or Failure or Arrest of Haemorrhage in 22 Patients Treated with Gastric Cooling*

Degree of Arrest	Under 50 Years Old			Over 50 Years Old				Total
	G.U.	D.U.	No Lesion on Ba Meal	G.U.	D.U.	No Lesion on Ba Meal	Varices	
Permanent ..	1	2	3	8	3	2		19
Arrest but delayed recurrence ..				1				1
Arrest but immediate recurrence..							1	1
Failure					1			1
Total.. ..	1	2	3	9	4	2	1	22

TABLE V.—*Degree of Success or Failure of Arrest of Haemorrhage in 22 Patients with Initial Conservative Management*

Degree of Arrest	Under 50 Years Old		Over 50 Years Old					Total
	D.U.	No Lesion on Ba Meal	G.U.	D.U.	No Lesion on Ba Meal	Varices	Ca.	
Permanent ..	4	2	3	3	3			15
Failure			1	3	1	1	1	7
Total.. ..	4	2	4	6	4	1	1	22

Table V indicates the comparable figures for the 22 cases initially treated conservatively. In this group there was permanent arrest of haemorrhage in 15 (68%) of the cases. In both groups failures were limited to patients over 50 years old.

In Fig. 4 it may be seen that the average for the total blood transfused to each patient in the gastric-cooling group is 8.6 units (540 ml. per unit) compared with 8.3 units in the conservatively managed group.

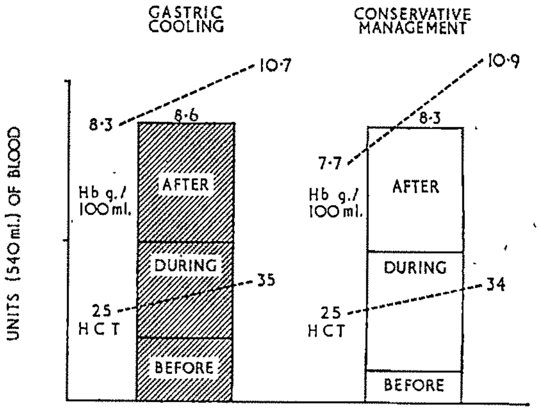

FIG. 4.—Comparison of the average amounts of blood transfused and the haemoglobin and haematocrit levels in the two groups of patients.

Evaluation of the Hypothermia Machine

The Cryocycle hypothermia system functioned very smoothly throughout the work. The plastic tubing, naturally, underwent some wear, but the second set was still being used at the end of the project. New balloons were used for each treatment; standard high-quality condoms proved ideal.

The most important temperature reading was that of the intragastric probe. If this remained steady and between 20 and 15° C. it was a good indication that coolant flow was proceeding satisfactorily. The average fall in rectal temperature was a few degrees only (as indicated in Fig. 3). However, it was possible for this to drift lower if external warming were not vigorous.

The hypothermia machine had the great advantage of being designed for gastric cooling only—that is, it was impossible when water was being circulated in the manner described for temperatures to fall below 0° C. This meant that the only immediate supervision necessary was that ice should be maintained in the bath.

Complications of Gastric Cooling

No catastrophic complications such as stomach rupture due to overdistension were encountered. This would seems to be almost impossible with the hypothermia machine used in this work.

Though cardiac infarction accounted for two deaths in patients who had gastric cooling this could quite reasonably be regarded as coincidental. Electrocardiography did not show any "injury potential" in association with gastric cooling.

Chest infection was the most common problem. During gastric cooling the intragastric balloon possibly gave some degree of left chest "splintage," though infection was not noticeably more marked on the left side. The patients were relatively immobilized in the supine position, and some inhalation of blood or mucus must have occurred quite often in spite of the care taken. In retrospect, moderate inclination of the upper trunk would probably have been wise.

When operations on the stomach were done urgently not long after gastric cooling had been under way there were no untoward findings in the gross or microscopical appearances of the stomach. Nor was there any evidence that postoperative healing was prejudiced by gastric cooling.

Discussion

In this study gastric cooling was carried out for a 24-hour period in all but a few of the cases so treated. This was because a review of the duration of treatment used by other workers (when they stated this) suggested this to be a reasonable time to control haemorrhage and minimize the chance of its immediate recurrence. It proved satisfactory to adhere to this period as a basis for comparative study, but probably a shorter period could be effective in some cases.

The definition of "massive" haemorrhage in terms of the blood loss, the patient's condition, and haemoglobin and haematocrit levels was arbitrary. It would not allow strict comparison with other reported series, but was a good practical guide for inclusion of patients in this series. Only after the patient had been accepted was the card indicating the method of treatment consulted.

Comparison between the two groups by examination of the "degree of arrest of haemorrhage" (Tables IV and V) would suggest that gastric cooling (three recurrences or failures) had a better success rate than the conservative group (seven failures), but statistical evaluation of these data (Table VI) indicates that any difference in the arrest of haemorrhage is not significant. Moreover, Table II shows that the eventual outcome (four deaths) was the same for each group.

TABLE VI.—*Statistical Evaluation of Data from Tables IV and V*

	Gastric Cooling	Conservative Management	Total
Permanent arrest	19	15	34
Degree of cooling	3	7	10
Total	22	22	44

$\chi^2 = 2{\cdot}07$. $P > 0{\cdot}10$.

In Fig. 4 the volume of blood transfused and the degree of anaemia show some minor differences (the conservative group had marginally lower haemoglobin levels at the start and throughout the period of review; less blood was transfused to those under 50 years—conservative group), but the overall *similarity* of the figures is striking. In particular an average of 8.6 units of blood was given to the gastric cooling group, while an average of 8.3 units was given to the controls.

It is evident that there is no significant difference between the two groups.

Summary

In a prospective study gastric cooling was used as an adjunct to initial conservative management of patients with serious upper gastrointestinal haemorrhage.

It has been shown that this method conferred no benefit on this group of patients compared with a similar group managed by expectant measures only.

This relative failure was not due to technical deficiencies; the hypothermia apparatus functioned smoothly and appeared to be superior to most earlier units.

The overall experience with this technique suggested that it may be useful when haemorrhage is persisting and there are strong reasons for avoiding operation.

This work was supported by a grant from the Medical Research Council. The Cryocycle hypothermia system, used throughout, was made available by Edward Weck and Co., Long Island City, New York. We are grateful also to the physicians and surgeons of Sefton General Hospital who referred cases and to Sister E. Edwards and Sister D. Markey for their expert nursing.

Lactobacillus casei C.S.F. Folate Activity

D. G. WELLS,* M.B., B.S.; H. J. CASEY,† A.I.M.L.T.

Brit. med. J., 1967, **3**, 834–836

Folic acid derivatives are essential components of enzyme systems required in the synthesis of several key precursors of both protein and nucleic acids. The effects of folate deficiency on human metabolism are potentially extremely severe (Woods, 1964).

It is known that the C.S.F. concentrates folate (Herbert and Zalusky, 1961). As the explanation for this is not understood and because of the recent interest in the relation between folate deficiency and neurological disease (Hansen *et al.*, 1964; Anand, 1964; Grant *et al.*, 1965), it was decided to study the C.S.F. folate activity in patients with neurological disease.

Materials and Methods

Samples of cerebrospinal fluid were obtained from patients in the following groups:

(1) *Hospital Controls:* The 30 patients in this group were admitted for investigation of neurological or psychiatric symptoms. However, in no instance was there evidence of active neurological disease. Several patients who had cerebrovascular accidents some months before admission were included in the control group. The C.S.F. was normal in respect of the total protein, cell count, and Pandy, Nonne–Apelt, and Lange tests.

(2) Patients with miscellaneous neurological diseases including: those with epilepsy being treated with anticonvulsants and those with multiple sclerosis and varied tumours of the nervous system.

The C.S.F. was centrifuged and the supernatant taken for analysis. Blood for the serum folate estimation was taken while the patient was fasting. The serum was separated within two hours from the time of venesection. Ascorbic acid (5 mg./ml.) was added to the C.S.F. and serum. Specimens were stored at −20° C. until analysis.

---

* Formerly Resident Pathologist, the National Hospital, Queen Square, London W.C.1.

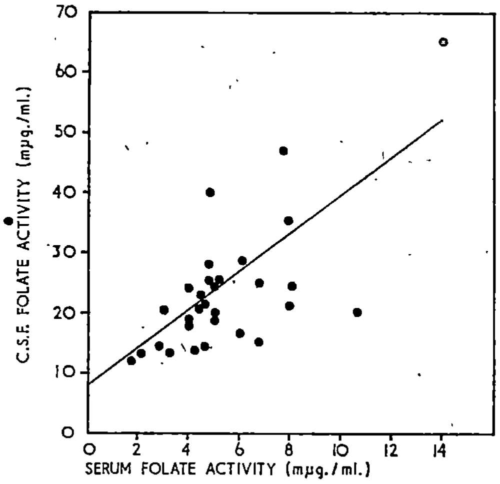
† Department of Haematology, the Hospital for Sick Children, Great Ormond Street, London W.C.1.

The serum folate levels were measured by microbiological assay with *Lactobacillus casei* (Waters and Mollin, 1961). The normal serum folate range is 5.9–21 mμg./ml. A serum folate of 4 mμg./ml. or above excludes severe folate deficiency. The C.S.F. folate levels were determined similarly, but the final dilution of the C.S.F. was one part in 160 as compared with one part in 80 for the serum folate estimation. If the colorimeter reading of the test sample did not correspond with the sensitive part of the pteroylglutamic acid curve the assay was repeated at an appropriate higher or lower dilution. Duplicate assays were performed on each C.S.F. and serum specimen, the mean figure being taken.

Results

Group 1

The range of C.S.F. folate activity in the 30 hospital control subjects was 12.6–67 mμg./ml. The mean C.S.F. folate level was 23.6 mμg./ml. (±2.0 mμg./ml. S.E.). The mean serum folate was 5.4 mμg./ml. (±0.46 mμg./ml. S.E.). The correlation between the C.S.F. and serum folate levels is shown in the Chart ($r=+0.7$; $P<0.001$). The calculated regression line has been drawn ($y=3.1\times+7.0$).



Relation between C.S.F. and serum *L. casei* folate activity.

Group 2

(A) *Epileptics Treated with Anticonvulsants* (10).—The mean C.S.F. folate level in 10 epileptic patients on anticonvulsant therapy was 16 mμg./ml. (± 2.1 mμg./ml. S.E.), which was significantly different from the mean C.S.F. folate level of the control subjects ($P<0.05$). The mean serum folate level was 4.7 mμg./ml. (±0.57 mμg./ml. S.E.). One-third of the patients had a C.S.F. folate level below 12.6 mμg./ml. Despite the effect of the anticonvulsants a correlation persisted between the serum and C.S.F. folate levels ($r=0.627$; $P<0.05$). The calculated regression line was $y=2.3\times+5.3$. Perhaps the most interesting epileptic patient studied was a woman who developed a cerebellar disorder with ataxia, nystagmus, and dysarthria while being treated with Epanutin and phenobarbitone. Intensive investigation (including air-studies) failed to suggest an alternative diagnosis to Epanutin intoxication. However, when the Epanutin therapy was curtailed no improvement resulted. Her serum and C.S.F. folate levels were 1 mμg./ml. and 4.2 mμg./ml. respectively. The serum vitamin B_{12} level was normal. Treatment with folic acid resulted in no objective improvement.

(B) *Multiple Sclerosis* (12).—The range of C.S.F. folate activity in the 12 patients with multiple sclerosis was 16–43 mμg./ml. The mean C.S.F. and serum folate levels were 21.6 mμg./ml. (±1.7 mμg./ml. S.E.) and 6.0 mμg./ml. (±0.83 mμg./ml. S.E.) respectively. The mean C.S.F. folate level was not significantly different from that of the control subjects ($P>0.05$). The correlation between the serum and C.S.F. folate activity in this small group was poor ($r=0.28$; $P>0.05$). Several of the patients were being treated with vitamin B_{12} injections and/or corticosteroids. This therapy or the underlying pathology may have been responsible for the lack of correlation.

(C) *Tumours of the Nervous System* (10).—The C.S.F. folate range in 10 patients with varied tumours of the nervous system was 7–27 mμg./ml. The mean C.S.F. folate level was 19 mμg./ml. (±1.9 mμg./ml. S.E.) while the mean serum folate level was 5.9 mμg./ml. (±1.1 mμg./ml. S.E.). The mean C.S.F. folate level was not significantly different from that of the control subjects ($P>0.05$). This group included patients with benign tumours and also those with malignant lesions. A patient with a low C.S.F. folate of 7 mμg./ml. and serum folate of 3.9 mμg./ml. had a spinal block due to metastases. When a laminectomy was performed tumour tissue was found invading the theca. In view of the known ability of tumour cells to metabolize folate it is not surprising that the correlation between the serum and C.S.F. *L. casei* folate activity was poor ($r=0.32$; $P>0.05$).

(D) *Miscellaneous Neurological Diseases.*—Smaller groups of patients suffering from polyneuritis (5), Parkinsonism (4), motor neurone disease (4), Friedreich's ataxia (1), tabes dorsalis (1), syringomyelia (1), trigeminal neuralgia (1), and acute necrotic myelitis (1) were also studied. Their C.S.F. folate levels with one exception fell within the range seen in the control subjects. The patient with a low C.S.F. folate of 12 mμg./ml. was an alcoholic with a peripheral neuropathy. His admission to hospital was prompted by the development of bilateral optic neuritis. A patient with neurological symptoms in whom no definite diagnosis could be made is of interest because she had a low C.S.F. folate level. She had pulmonary tuberculosis and was being treated with antituberculosis drugs (isoniazid, para-aminosalicylic acid, and streptomycin). She gave a short history of paraesthesia of her hands and feet, suggesting an early peripheral neuropathy. However, electromyographic studies showed no evidence of peripheral neuropathy. Her C.S.F. folate was 8 mμg./ml. and the serum level 1.3 mμg./ml. The serum B_{12} level was 660 μμg./ml. When her drug therapy was curtailed and her diet improved her symptoms were alleviated.

Discussion

It remains unexplained why folate deficiency does not cause a clearly defined neurological picture allied to that of subacute combined degeneration of the cord. Neurological disease associated with folate deficiency has now been documented by a few authors (Anand, 1964 ; Hansen *et al.*, 1964). Grant *et al.* (1965) have discussed this association and described three cases with mainly sensory signs and symptoms which improved after oral folic acid.

There is a positive correlation between the serum and C.S.F. folate activity. Despite this correlation it is reasonable to assume that the C.S.F. folate level will more accurately reflect the folate content of the nervous system than the serum level. It is therefore advantageous to assay the C.S.F. folate activity when investigating the relation between disorders of the nervous system and folate deficiency.

The major difficulty of investigating such a relation is that folate deficiency may be coincidental and quite unrelated to the nervous disorder. Therefore, before attributing a neurological disorder to folate deficiency it is essential to exclude other aetiological factors, including deficiency of vitamin B_{12}, pyridoxine, and thiamine.

As a group the epileptics showed the largest proportion of subnormal folate levels. Mannheimer *et al.* (1952) and Badenoch (1954) were the first to note the occurrence of megaloblastic anaemia in epileptic patients who were being treated with anticonvulsant drugs. More recently there have been reports of folate deficiency in many non-anaemic drug-treated epileptics (Hawkins and Meynell, 1958 ; Klipstein, 1964 ; Malpas *et al.*, 1966 ; Reynolds *et al.*, 1966). The findings in our small group of epileptics are in agreement and also show that evidence of disturbed folate metabolism may be detected in the C.S.F. This is of interest, as Reynolds *et al.* (1966) have postulated that the interference with folate metabolism may be related to the therapeutic action of anticonvulsants, and at the same time may be responsible for some of the mental symptoms that occur in these patients.

One of the epileptic patients being treated with phenobarbitone and Epanutin subsequently developed a cerebellar syndrome which failed to resolve when the Epanutin was curtailed. Permanent neurological dysfunction resulting from Epanutin has been described by several authors, including Morris *et al.* (1956) and Putnam and Rothenberg (1953). Rats and cats when subjected to prolonged intoxication showed the loss of the Purkinje cells and degenerative cell changes in the cerebellum (Kokenge *et al.*, 1965). The patient, described above, was found to have a C.S.F. folate level of 4.2 mμg./ml. It is suggested that the toxic effect of Epanutin is due to its interference with folate metabolism.

Sobotka *et al.* (1958), by means of a microbiological assay utilizing a thermophilic bacillus, found raised C.S.F. folate levels in 34 out of 42 cases of multiple sclerosis studied. The C.S.F. folate levels in the 12 multiple sclerosis patients studied all fell within the range seen in the control subjects. Of 10 patients with varied tumours of the nervous system, only one had a low C.S.F. folate level. This patient had a spinal block due to metastases. It is probable that the tumour cells were metabolizing the C.S.F. folate.

The C.S.F. folate level in five patients with polyneuritis of different aetiology with one exception fell within the range seen in the control subjects. The exception was an alcoholic with a severe peripheral neuropathy and evidence of an early hepatic cirrhosis. Folate deficiency in combination with a deficiency of other vitamins has already been noted in cases of alcoholic peripheral neuropathy by Fennelly *et al.* (1964). No improvement resulted when the patient was given oral folic acid.

The association of folate deficiency and tuberculosis has been noted by Roberts *et al.* (1966). They concluded that folate deficiency was not due to the chemotherapy but to the disease process itself, or a poor diet. Whether the paraesthesiae and dysaesthesia in the case described were due to the folate deficiency cannot be answered, as the symptoms may have been the presenting feature of a disease, such as multiple sclerosis, which spontaneously remitted.

Summary

The serum and C.S.F. *Lactobacillus casei* folate activity has been assayed in 30 hospital control patients. A positive correlation between the C.S.F. and serum folate activity has been shown to exist.

The C.S.F. folate activity has been assayed in miscellaneous neurological diseases. Drug-treated epileptic patients showed a high proportion of subnormal C.S.F. levels. Groups of patients with multiple sclerosis, miscellaneous tumours, etc., were found to have a mean C.S.F. folate level which did not differ significantly from that of the control group.

The association between neurological disorders and folate deficiency is discussed.

It is a pleasure to thank Professor J. N. Cumings and Dr. R. M. Hardisty for their help and advice in the preparation of this manuscript.

Gritti–Stokes Amputation in Atherosclerosis: a Review of 237 Cases

PETER MARTIN,* V.R.D., M.CHIR., F.R.C.S.; STUART RENWICK,† M.B., F.R.C.S., F.R.A.C.S.
E. MAELOR THOMAS,‡ F.R.C.S.

Brit. med. J., 1967, 3, 837–838

Operation

For the past 15 years we have used the Gritti–Stokes amputation extensively for threatened or established gangrene in atherosclerosis because the anatomy of the collateral circulation in limbs gangrenous from atherosclerosis makes primary healing usual. This is because the femoro-popliteal artery is nearly always obstructed, in which circumstance the distal part of the limb receives its blood supply through the collateral vessels which bypass this vessel. Collateral vessels normally pass in the intramuscular planes, but where there are no such planes they are forced into subcutaneous tissues (Fig. 1). So when the femoro-popliteal artery is blocked the collaterals are found in among the muscles where these surround the femur above or the tibia and fibula below; but in the region of the knee joint, where the bones are not so surrounded, they are forced into the subcutaneous tissues. Flaps fashioned from skin supplied by such enlarged collaterals can be expected to heal better than flaps not so nourished (Martin and Wickham, 1962). Mortality and morbidity have been low, and in addition a useful stump results. Others have advocated this operation (Jones, 1961; Middleton and Webster, 1962; Nayman, 1964; Lishman, 1965).

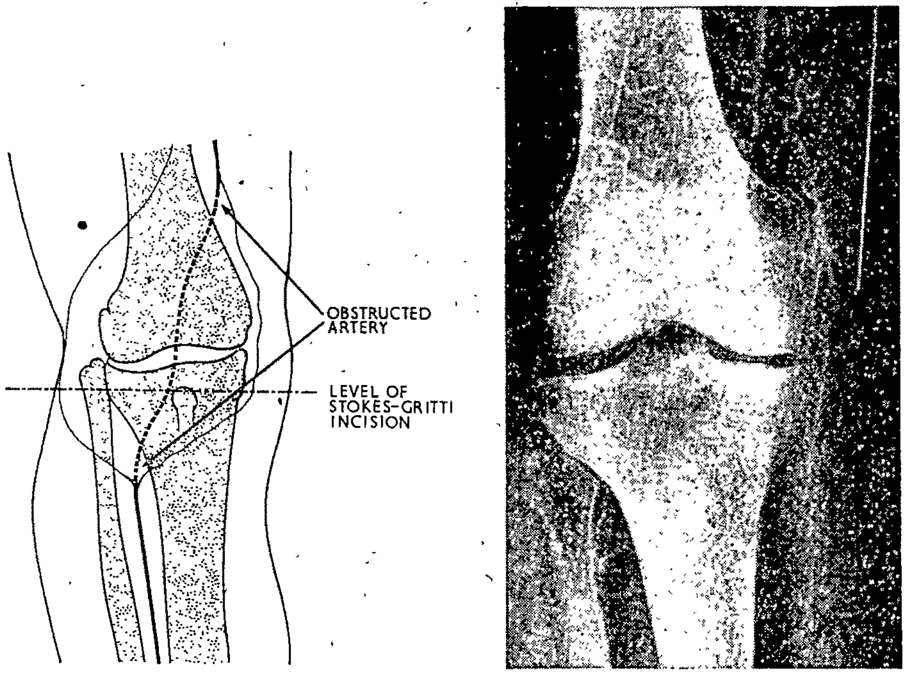

FIG. 1.

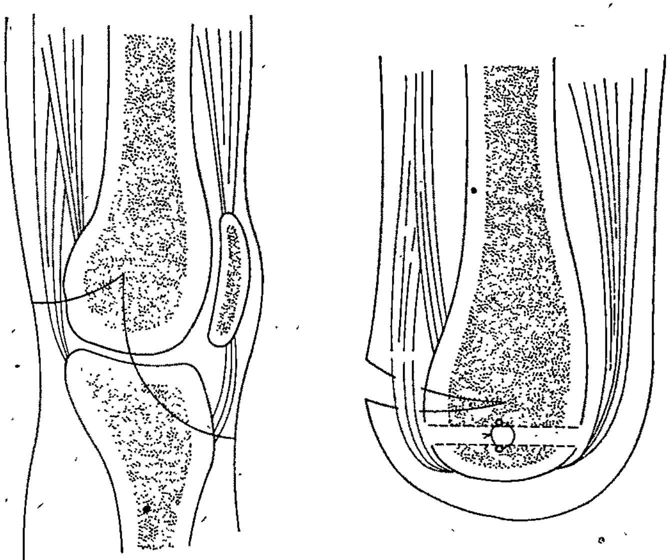
The U-shaped incision begins at the adductor tubercle, passes downwards, and then across the mid part of the tibial tubercle. It then ascends on the outer aspect of the lower end of the femur to a point corresponding to the adductor tubercle on the inner aspect. The incision goes down to bone. The two ends of this incision are joined behind the knee by an incision convex downwards, its lowest part about 1 in. (2.5 cm.) distal to its extremities. The knee joint is then acutely flexed and the lateral and cruciate ligaments of the joint are divided. The tibia dislocates forwards, the posterior capsule and the ligaments are divided, and then from in front the vessels and nerves in the popliteal fossa are also divided. The vein—but not the artery, which is already thrombosed—requires a ligature. The sciatic nerve may need a ligature. From the back the hamstring muscles are divided, and the amputation is completed.

The end of the femur is then sawn through at the level of the adductor tubercle. The articular surface of the patella is sawn off. With a bradawl, holes are bored through the lower end of the patella and the posterior lip of the femur so that the patella can be stitched with stout silk to keep it in place over the end of the femur, and to the popliteal ligament is sewn the hamstring tendons so that their extension function is preserved. The wound is sutured in one layer, and a suction-drain is inserted through one angle (Fig. 2).

The drain is removed, without disturbing the dressing, on the second day, and the dressings on the tenth day after operation. The patient is allowed up on the second day and to walk with crutches as soon as he can manage. Within two weeks he should be measured for his pylon. Little blood is lost, postoperative shock is slight, and for some reason phantom limb is not conspicuous.



THE INCISION
THE STUMP

Patients

Gritti–Stokes amputations have been done on 237 occasions between 1957 and 1966 at the Hammersmith and Chelmsford and Essex Hospitals. During this period 20 primary mid-thigh amputations and 21 below-knee amputations were performed for all varieties of vascular disease. Mid-thigh amputations were done when there was infection, sometimes by gas-forming organisms, and when non-infected gangrene of the limb extended to the level of the upper third of the tibia. Below-knee amputations were rarely done for arteriosclerotic gangrene. Bilateral amputations were done on 20 patients.

The average age of patients was 67 years, with a range from 41 to 89 years. Ten per cent. of the patients had had a previous cerebrovascular episode, and 87% had evidence of ischaemic heart disease. Forty-four (20%) suffered from diabetes. The ratio of male to female patients was 5 to 1.

Indications.—The operations were performed for gangrene, rest pain, or indolent ischaemic ulceration.

Results

There were 14 deaths in the first two weeks after amputation, a mortality rate of 5.9%. Primary healing occurred in 176 patients (78.8%). In 27 healing was delayed by minor skin sepsis but was eventually complete, giving a total healing rate of 91%.

In 17 patients (7.7%) sepsis or failure to heal led to a higher amputation, and we have one patient with an unhealed ulcer who will probably come to higher amputation. Two patients have wound sinuses with radiological evidence of osteomyelitis, but they use their prostheses without discomfort. One patient has a mobile patella, probably due to incomplete removal of the cartilage from the joint surface of this bone.

These results are summarized in the Table.

Results in 223 Amputations in which Patient Survived 14 *Days or Longer*

Complete healing	Primary healing	176	(78·8%)
	Delayed healing	27	(12·2%)
Incomplete healing	Stump sinus	2	(1·3%)
	Persistent ulcer	1	
	Failure needing re-amputation	17	(7·7%)

Subsequent Use of the Stump.—During the past 12 months we have fitted seven patients with an immediate prosthesis in association with the Limb Fitting Centre at Roehampton. All these patients were using their stumps for walking within 14 days of amputation. They will form part of a later communication from Roehampton.

Of the remaining 230 patients 123 (55%) were fitted with a prosthesis which they use. At least 29 (12.5%) were recorded as having returned to gainful employment.

Discussion

The operative mortality in this series was 5.9%, which is in close agreement with that reported by others of between 6 and 8% (Middleton and Webster, 1962 ; Lishman, 1965). This low mortality rate is probably due to the fact that the operation is easily and rapidly performed, that there is minimal loss of blood, and that there is no injury to muscle substance. The mortality for mid-thigh amputations is much higher, as Lishman (1965) showed, varying from 18 to 42% (Gilchrist, 1961 ; Ham *et al.*, 1964 ; Otteman and Stahlgren, 1965 ; Lishman, 1965).

The healing rate was 91%—78% by first intention. Others have reported primary healing rates for this operation varying between 76 and 90% (Middleton and Webster, 1962 ; Nayman, 1964 ; Lishman, 1965). The reported healing rates for mid-thigh amputation vary from 53 to 72% (Dale and Jacobs, 1962 ; Ham *et al.*, 1964).

Reamputation at a higher level was necessary in 7.7% of patients. This contrasts markedly with a reamputation rate of between 29 and 38% for below-knee amputations (Tolstedt and Bell, 1961 ; Dale and Jacobs, 1962 ; Lishman, 1965).

As regards disarticulation through the knee, we have been disappointed because primary healing failed to occur in the few of which we have had experience. This may be due to the fact that the skin incision traverses skin which does not enjoy the liberal blood supply found with a Gritti–Stokes incision. Furthermore, the only account of a series of disarticulations that we have seen recorded only 15 patients with primary healing out of 27 patients undergoing operation (Taylor, 1967). In addition, we have evidence that some of the successful cases would in fact have been better if part of the condyles of the femur had been removed to avoid pressure on the skin covering them. If the technique of disarticulation is going to be altered so that the condyles do in fact have to be removed to some extent, then this operation will approximate very closely to the Gritti–Stokes amputation here described. We await with interest reports of amputation by disarticulation.

It is also interesting to note that in the interim report from Roehampton of the results of immediate fitting of prostheses the only type of amputation which was successful in every case was the Gritti–Stokes, though certainly the numbers were small.

Thus the Gritti–Stokes amputation has a low mortality, a high healing rate, and a low reamputation rate. The stump, too, is a useful one.

Rehabilitation is facilitated by the availability of a lightweight articulated prosthesis. This is partially ischial and partially end-bearing, the latter factor ensuring proprioception. The knee joint can be arranged so that flexion is at the same level as that of the opposite side.

If bilateral amputation becomes necessary the Gritti–Stokes amputee can get about in the house on his knees or with rockers and can turn over in bed, which a bilateral mid-thigh amputee cannot do.

Summary

The results of 237 Gritti–Stokes amputations for atherosclerotic gangrene are presented. Primary healing occurred in 78.8%, with a total healing rate of 91%. A mortality of 5.9% and a reamputation rate of 7.7% compare more than favourably with similar series of below-knee or mid-thigh amputations. The immediate fitting of a prosthesis on the operating-table should promote earlier mobility and lower the mortality rate still further.

Medical Memoranda

Familial Myasthenia Gravis

Brit. med. J., 1967, 3, 839–840

Myasthenia gravis is described in textbooks of medicine and neurology as a disease of the third and fourth decades of life. Its occurrence in infancy and childhood is rare. During 1900–65 only 54 cases in 22 families have been reported. To find the disease in more than one generation in the same family is rarer still, only four such instances so far having been recorded. Myasthenic symptoms persisting from the time of birth (congenital myasthenia) is also rare. The following four cases of myasthenia gravis in a brother, sister, and two children of an unaffected sister are of interest from these various aspects of the disease.

CASE REPORTS

Case 1.—A man aged 28 attended the Medical College Hospital, Calicut, for drooping of the upper lids, difficulty in focusing near objects, and blurring of vision of two years' duration. On direct questioning he admitted that he had had slight drooping of the eyelids for at least 12 years. He denied any weakness in the limbs or difficulty in swallowing. The history of his past illness showed nothing contributory. One of his sisters, aged 17 (Case 2), had had the same complaints since the age of about 5 years, as also had two nephews (Cases 3 and 4).

General physical examination showed nothing contributory. Bilateral ptosis was present. The ocular movements were almost completely absent in all directions in both eyes. He could not look to one side or the other without turning his head. The pupils were normal. There was no other abnormality in the central nervous system. Examination of the other systems did not reveal any abnormality. Laboratory investigations were negative. The *x*-ray picture of the chest was normal. About 20 minutes after he was given neostigmine subcutaneously (2.5 mg. mixed with 0.5 mg. of atropine) he could lift his eyelids normally and the ocular movements were restored to complete range. The effect lasted for about three hours. He was put on neostigmine bromide 10 mg. thrice daily and ephedrine 30 mg. twice daily. He has since remained significantly improved.

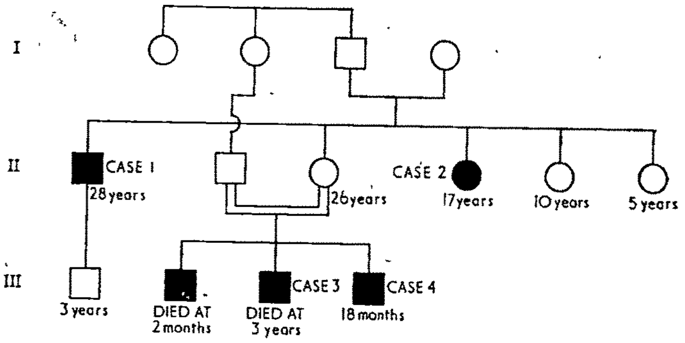
Case 2.—A 17-year-old unmarried girl, sister of Case 1, had had ptosis and restricted movements of the eyeballs from the age of 12 years. The disability was worse towards the evening. From the age of 15 tiredness and weakness of both upper limbs were also noticed. General examination did not reveal any abnormality. Ptosis was present on both sides. Movements of the eyeballs were very restricted in all directions. The pupils were normal. The muscles of the upper limbs showed diminution in motor power not limited to any specific muscle groups. There was no wasting. The deep reflexes were sluggish. Physical examination did not reveal any other abnormality in the central nervous system or any other system. *X*-ray examination of the chest showed widening of the superior mediastinum consistent with a thymic shadow. Other investigations were negative. As in Case 1, there was prompt relief of symptoms and restoration of ocular movements and disappearance of ptosis after neostigmine injection. The patient improved from the regular administration of neostigmine bromide 10 mg. thrice daily.

Case 3.—A 2-year-old boy, son of a normal sister of Cases 1 and 2, was noticed to have ptosis from birth. The parents found that he could not look to one side or the other without turning his head. The extremities were floppy. He was not yet steady in his walk and tended to fall. Physical examination showed bilateral ptosis, restriction of ocular movements in all directions, and hypotonia of the limb muscles. The deep reflexes were sluggish. No other abnormality was detected. The *x*-ray picture of the chest was normal. The ocular movements and the strength of the muscles improved and the ptosis disappeared after the injection of 1.25 mg. of neostigmine. The parents were advised to give the child 5 mg. of neostigmine bromide twice daily. He was doing well, but 11 months after the first admission he had an attack of pneumonia and died.

Case 4.—An 18-month-old boy, younger brother of Case 3, was brought to us immediately after that brother had died of bronchopneumonia. The cases, as stated by the parents, were similar. The boy was found to be weak and slow in his movements and to have had bilateral ptosis since birth. The weakness became more pronounced towards the evening, when the ptosis was also more prominent. Physical examination showed hypotonia of muscles, ptosis, external ophthalmoplegia, and sluggish deep reflexes. An *x*-ray picture of the chest was normal. There was prompt response to a subcutaneous injection of 1.25 mg. of neostigmine, with disappearance of ptosis and external ophthalmoplegia.

FAMILY TREE

The family tree is shown in the Chart. The affected members are shown in black. The members of generation I were examined and all were found to be normal. In this generation there were no marriages between relations. The history did not suggest the presence of similar illness in the previous generation. The disease presumably made its first appearance in generation II, to which Cases 1 and 2 belong. The other members of generation II were examined and found to be normal. The unaffected sister of Cases 1 and 2 and her husband are first cousins. They had three male children in generation III. All were affected by the disease. Their first child died at the age of 2 months. We did not see the child, therefore the case is not reported here. Case 3 died at the age of 3 years. Case 4 is still alive and is being followed up. The 3-year-old son of Case 1 is normal.



FOLLOW-UP

Cases 1, 2, and 3 came under our observation in August 1963 and Case 4 in September 1964. Case 3 died in July 1964. Cases 1, 2, and 4 are still being followed up. They are on maintenance treatment with neostigmine and ephedrine. Case 2 married recently, and it will be of interest to observe the children of the marriage.

COMMENT

The myasthenic syndrome has often been reported in neonates born of myasthenic mothers since Strickroot *et al.* (1942) reported the case of a mother with myasthenia gravis whose newborn child developed signs of generalized weakness on the third day of life and died on the seventh day from respiratory failure. Since in these cases the symptoms are transient and are probably due to a curare-like substance transferred through the placenta it is not correct to include these cases as familial myasthenia gravis. The first report of familial incidence of myasthenia gravis is that of Oppenheim (1900). Celesia (1965) reported the cases of a brother and sister suffering from myasthenia, and reviewed all the cases of familial myasthenia gravis recorded in the literature up to that time, bringing the total number to 54, distributed among 22 families.

The four cases reported here bring the total so far to 58 cases in 23 families. Since in these cases the lesion is mostly confined to the ocular muscles the problem of differentiation from ocular myopathy (Kiloh and Nevin, 1951) arises. But the tendency of the disability to worsen towards evening and the favourable response to the administration of neostigmine favoured the diagnosis of myasthenia gravis.

Certain other observations may be made in these cases. They represent individuals of two generations. In only four of the 22 previously reported families were two generations affected. Peters (1906) reported the cases of two sisters, two brothers, and the father. Noyes (1930) reported cases of a brother, sister, and father ; Eaton (cited by Levin, 1949) the cases of a father and son ; and Foldes and McNall (1960) the cases of two sisters and their mother. The present report is the fifth instance of familial myasthenia gravis affecting more than one generation. Celesia (1965) observed that in instances where more than one generation is affected by the disease the onset is in adulthood. Our cases, however, prove otherwise, for Cases 3 and 4 showed myasthenic symptoms from birth.

The first case of congenital myasthenia was reported by Bowman (1948). Levin (1949) considered three types of myasthenia gravis in children. They are the transient neonatal myasthenia, the familial myasthenia occurring in siblings, and the ordinary or acquired myasthenia. Acquired non-familial myasthenia is rare in childhood ; but among 41 cases of familial myasthenia limited to one generation, in 20 the onset of the disease was in infancy and in 12 in childhood or adolescence (Celesia, 1965). All our four cases had their onset before the age of 16 years, thus proving the early age of onset in familial myasthenia. This difference of the familial cases from the non-familial ones may be of importance from the genetic point of view.

Levin (1949) used the term "congenital myasthenia" to describe the form of myasthenia which begins at birth (or before), and is characterized by a mild onset, marked external ophthalmoplegia, partial ptosis, and symmetrical weakness of the involved muscle groups. In contrast to the usual myasthenia gravis it is not progressive and does not show remissions. There is a dramatic response to the administration of neostigmine. Though the basic defect is the same the disease may be different from the myasthenia gravis described by Erb (1879) and Goldflam (1893). Among the cases of familial myasthenia gravis reported there are only six patients in four families in whom the disease was present from birth and hence qualify as congenital myasthenia. These were reported by Levin (1949, two cases in a family), Osserman (1961, three cases in two families), and Walsh and Hoyt (1959, one case in a family with four affected members). In all these cases ptosis, ophthalmoplegia, and generalized weakness were the prominent symptoms. Our Cases 3 and 4 are the seventh and eighth cases of congenital myasthenia gravis among the familial myasthenics recorded to date. Though Levin thought it probable that these cases would show marked improvement in course of time, one of our patients died at the age of 3 years from an intercurrent respiratory infection.

So far there is only one report of thymus enlargement in familial myasthenia gravis. At necropsy Marinesco (1908) noticed persistence of the thymus, and the histopathological features suggested hyperplasia. In our Case 2 the x-ray picture of the chest showed widening of the superior mediastinum consistent with enlargement of the thymus.

Our thanks are due to Dr. R. Ananthanarayanan, Principal, Medical College, Calicut, and to Dr. M. Thankam, Superintendent, Medical College Hospital, Calicut, for allowing us to report these cases.

Self-inflicted Oleogranuloma of Breast

Brit. med. J., 1967, **3**, 840–841

While oleogranuloma of the breast is a well-recognized condition in the Orient, it must be unusual to encounter a case in Britain. The following case of bilateral granulomata of the breasts in an English woman is especially interesting, in that the condition was self-inflicted after she had read an article in the lay press which mentioned that Japanese women have had petroleum jelly injected into their bosoms to increase their size.

CASE REPORT

An unmarried woman aged 26, the mother of twins aged 6 years, was concerned about the flatness of her chest and consulted a plastic surgeon who, 10 years previously, had removed a tattoo from her arm. As she had recently been under psychiatric treatment, it was thought unwise to advise operation at that time. She therefore decided to treat herself by making multiple injections of warm, molten petroleum jelly into each breast, using a 20-ml. syringe and intramuscular needles which she had purchased for this purpose. Pain was not experienced at the time of the injection, but several days later she described tenderness and discomfort in both axillae. This was followed during the next few months by a severe reaction, more marked on the right side, and the breasts became nodular, painful, and inflamed, and finally sinuses formed exuding petroleum jelly (Fig. 1).

Mammograms showed extensive cystic changes in the breasts, presumably due to grease globules (Fig. 2). *Treatment :* Bilateral simple mastectomy was advised but rejected by the patient. It was therefore decided to try to evacuate the grease globules through several small incisions. Each breast was operated on separately, with an interval of three months between operations.

At operation some of the oleogranulomata were so well defined that they could be dissected free intact (Fig. 3). Other areas of the breast had diffuse fibrotic changes with infiltration of grease, and the best that could be done here was to extrude as much of the petroleum jelly as possible. The wounds were closed and a small corrugated rubber drain was inserted. Postoperative antibiotic therapy was given, though bacterial culture of the excised tissue was sterile. The wounds healed by first intention and the breasts have remained free from further discharge. As expected, the breasts were still quite flat and the patient was still seeking mammoplasty.

Histology of the removed lumps showed the typical appearances of oleogranulomata, there being multiple cystic areas surrounded by dense fibrous tissue and foreign body giant cells (Fig. 4).

COMMENT

As early as 1903 Gersuny suggested that paraffin waxes of high melting-point could be used as a subcutaneous implant to alter surface contours. It was soon found, however, that in a proportion of cases the late results were far from satisfactory owing to the formation of oleogranulomata, followed by ulceration of the overlying tissues and persistent discharging sinuses.

While this method of mammoplasty has been abandoned by medically qualified persons, occasionally one comes across such a case as that described, but this is more common in the East (Tinckler and Stock, 1955).

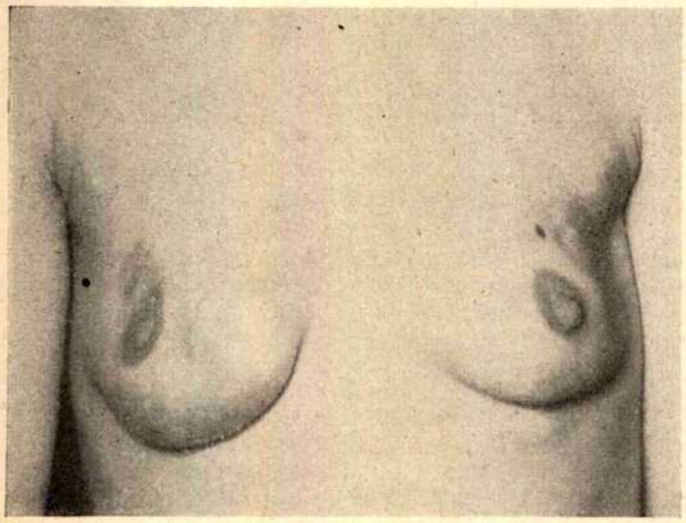

FIG. 1.—Induration and sinuses in both breasts after an intramammary injection of petroleum jelly.

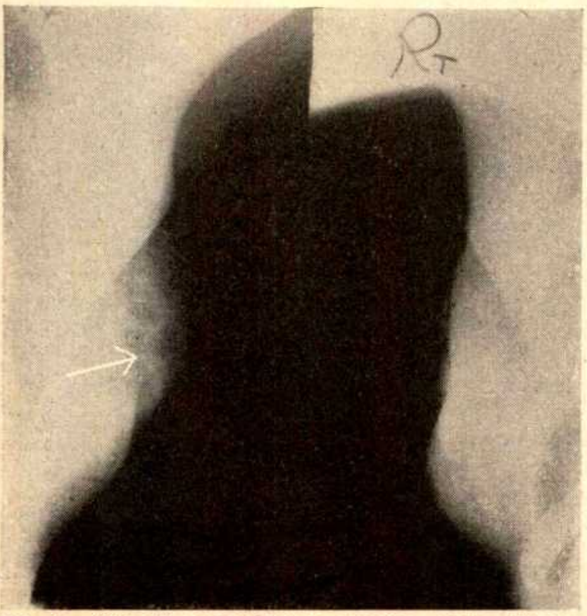

FIG. 2.—Bilateral mammograms: extensive cystic changes shown on left side (arrowed) presumably due to grease globules.

Histologically there is no difference between the oleogranuloma so formed and that encountered as a result of accidental injection with a high-pressure spray gun. Another less abstruse cause of oleogranulomata is the injection of haemorrhoids with phenol in almond oil, a procedure which is not without its hazards.

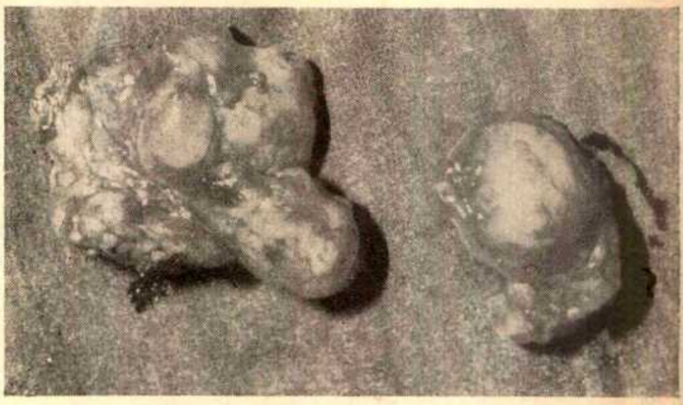

FIG. 3.—Two oleogranulomata dissected intact from the breast.

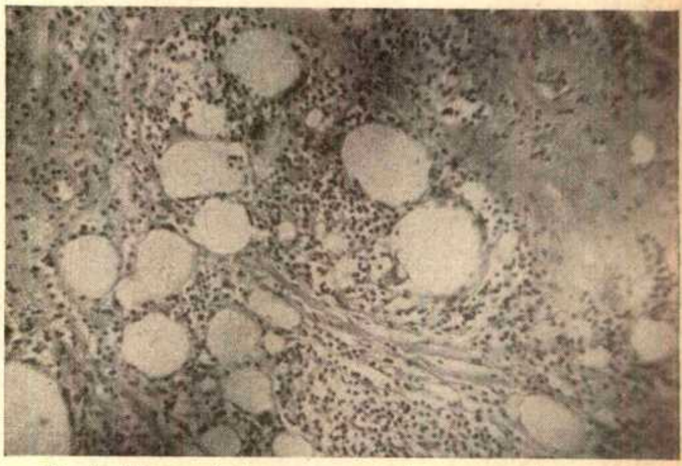

FIG. 4.—Microscopical appearance of oleogranuloma (low power).

Oleogranulomata in the main are themselves relatively harmless except for the mechanical difficulties they may cause, depending on their site. If, on the other hand, ulceration of the overlying skin occurs with the formation of a persistent discharging sinus, then neoplastic change sometimes occurs at the edge of the ulcer so formed (Vinogradov, 1936).

We would like to thank Professor F. E. Stock for his help and criticism in the preparation of this paper, and Mr. J. Cosbie Ross for allowing us to report it.

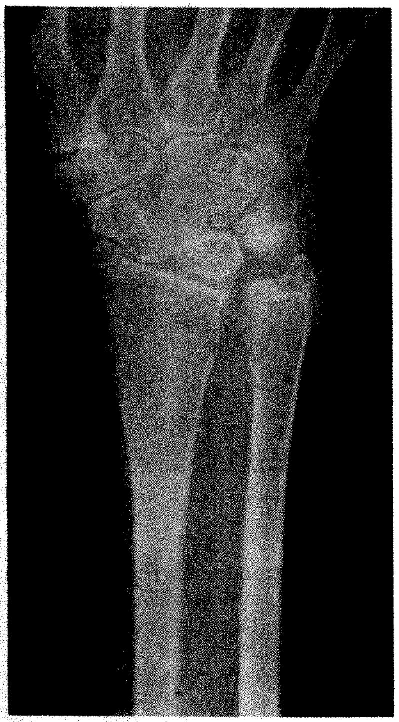
Oldest Pituitary Dwarf?

Brit. med. J., 1967, 3, 842

The oldest presenting age of idiopathic pituitary dwarfism in a series reported by Albert *et al.* (1953) was 41. Faurbye (1946) reported the case of a 61-year-old woman and Hawley (1963) the case of a 67-year-old man. We describe the case of a man with hypopituitary dwarfism who first became ill at the age of 77 years, responded excellently to hormonal replacement therapy, and subsequently developed a carcinoma of the oesophagus.

CASE REPORT

The patient was admitted to hospital on 21 July 1965 with a history of increasing dyspnoea, swelling of the ankles, weakness, constipation, and increased sensitivity to cold. He had never shaved or experienced libido, there was no relevant past history, nor was there any family history of dwarfism. He was born on 12 February 1888 in Melbourne and had lived a life of relatively unrestricted activity successfully managing a small plant nursery for many years. In appearance he was a gnome-like man, slightly drowsy, with waxy wrinkled skin and a high-pitched voice. Body hair was absent and the testes and penis were prepubertal in size and appearance; his total height was 134 cm., pubic-to-floor 68 cm., and span 134 cm. Further examination showed nothing abnormal apart from a body temperature of 36.1° C., a bradycardia, and sluggish tendon reflexes.



Radiograph of left wrist showing persistence of the epiphysial lines in the radius and ulna.

On admission, serum electrolytes were: sodium 121 mEq/l.; potassium 4.4 mEq/l.; chloride 87 mEq/l.; CO_2 combining power 25 mEq/l. Other relevant investigations were: serum urea 72 mg./100 ml.; haemoglobin 13.3 g./100 ml.; white cell count 5,000/cu. mm.; E.S.R. 34 mm. in one hour (Westergren); serum cholesterol 312 mg./100 ml.; protein-bound iodine 2.4 μg./100 ml.; 24-hour ^{131}I thyroid retention 17%; E.C.G.—sinus bradycardia low voltages and flat or inverted T waves; urinary 17-ketosteroids 1.8 mg./24 hours; 17-hydroxycorticosteroids 4.8 mg./24 hours; urinary gonadotrophins absent at 4.0 mouse units per day; *x*-ray film of skull—normal-sized sella turcica with no other abnormality; skeletal survey—persistence of the epiphysial lines in the radius and ulna (see Fig).

Over the next two days he became stuporous, and a diagnosis of hypopituitarism with water intoxication was confirmed by a serum sodium of 102 mEq/l. and a serum chloride of 74 mEq/l. Treatment was begun with fluid restriction, cortisone acetate 12.5 mg. b.d., and triiodothyronine 100 μg./day. Within 48 hours he became restless and disorientated, with visual hallucinations and a raised temperature. Clinical examination did not reveal an infective process, and a diagnosis of an acute brain syndrome due to cortisone was made. Cortisone was decreased, fluids were further restricted, and large doses of chlorpromazine, and subsequently a combination of haloperidol (Serenace) and benzhexol (Artane), were used. Acute delirium persisted for three days, despite correction of serum electrolytes, and then gradually improved. His further course was complicated by the development of an iron-deficiency anaemia and marked peripheral oedema. The faeces were positive for occult blood, but contrast *x*-ray films at this time revealed no definite abnormality of the gastrointestinal tract. After blood transfusion there was a marked diuresis and general improvement.

At the time of his discharge from hospital, six weeks after admission, he was alert and cheerful, no abnormality was detectable in the cardiovascular or central nervous systems, and the serum electrolytes were normal. He was maintained on prednisolone 1 mg. t.d.s. and L-thyroxine 0.1 mg. a day, and remained very well until 12 months after discharge, when he complained of dysphagia, indigestion, and loss of 1 st. (6.4 kg.) in weight over a period of six weeks. Barium-meal examination revealed a constriction and filling defect at the lower end of the oesophagus. Biopsy showed a poorly differentiated squamous-cell carcinoma of the oesophagus invading the mucosa and muscle layers.

COMMENT

The diagnosis of hypopituitary dwarfism in this man was established by his history and investigations. In the absence of any sign of abnormality of the pituitary fossa it would seem reasonable to assume that this is "idiopathic." It is remarkable that at least seven decades elapsed before medical attention was required for the treatment of this degree of pituitary insufficiency. It is also of interest that although there was epiphysial fusion on *x*-ray examination there was also persistence of the epiphysial lines in the radius and ulna comparable to the skeletal age standard for 18 years in the radius and 17 years in the ulna (Greulich and Pyle, 1959). The case reported by Faurbye (1946) had similar radiographs, while Hawley's (1963) case showed widespread failure of fusion of the epiphyses throughout the skeleton.

The reason for his deterioration, resulting in admission with water intoxication due to corticosteroid deficiency at this particular time, remains uncertain, but the presentation is very similar to Hawley's (1963) case. The development of an acute brain syndrome has been seen by one of us (F. I. R. M.) in several severely hypopituitary adults started on doses of cortisone greater than 25 mg./day, and it is likely that this dose was excessive in this patient.

So far as we can determine this man is the oldest patient recorded in the medical literature with idiopathic hypopituitarism and dwarfism. The development of a carcinoma in the oesophagus some 12 months after the beginning of replacement therapy with corticosteroids and thyroxine at the age of 77 years is of interest. As a barium-meal examination at the time of his original admission was normal, the possibility that there was some aetiological relation between the substitution therapy and the progress of his carcinoma deserves consideration.

We should like to thank Dr. J. H. Bolton for his kind permission to report this case.
